atom in the first electronically excited state, $O(^1D)$. The primary reason for the extreme importance of $O(^1D)$, which is present in very small concentrations, is that it reacts with highly unreactive atmospheric species, such as H_2O and N_2O , to create free radicals. Free radicals are very reactive and are the primary initiators of chemical changes in the lower atmosphere. Specifically, the OH radical in the stratosphere and troposphere and NO (and eventually all nitrogen oxides) in the stratosphere are produced mostly from the reactions of $O(^1D)$.

The OH radical is immensely important in the atmosphere for the following reasons: (1) OH is the most important initiator of the atmospheric degradation of the majority of natural and anthropogenic trace gases in the troposphere, (2) OH reactions provide the pathways that interconvert active and inactive forms of catalysts that are responsible for stratospheric ozone removal, (3) OH is directly involved in catalytic destruction of stratospheric ozone, and (4) OH is critical for initiating the sequence of reactions that photochemically generate tropospheric ozone. Similarly, nitric oxide (NO) is a crucial ingredient of the stratosphere. Once formed via the reaction of $O(^1D)$ with N_2O , it takes part in direct ozone destruction, suppresses the ozone destruction by halogens, and is a key chemical reactant. Therefore, $O(^1D)$ is a critical reactant in the Earth's atmosphere. The major source of $O(^1D)$ in the atmosphere below ~ 40 km is the photolysis of ozone in the Hartley and Huggins bands that are indicated in [Figure 1](#). (Note: The ground state of oxygen atom, $O(^3P)$, does not react rapidly with most atmospheric species and plays a much less important role in transforming chemicals in the atmosphere. But, its recombination with O_2 to make ozone is the primary pathway for ozone formation throughout the atmosphere.)

Photodissociation of Ozone

Definition of Absorption Cross Sections, Quantum Yield, and Photolysis Frequency

Before examining the photochemistry of ozone, it is necessary to define a few terms that are commonly used. The 'absorption

Figure 1 Absorption cross section of ozone between 230 and 800 nm at room temperature, taken from Burrows, J.P., Dehn, A., Deters, B., Himmelmann, S., Richter, A., Voigt, S., Orphal, J., 1999. The band systems, commonly referred to as Hartley, Huggins, Chappuis, and Wulf bands, are shown in the figure taken from the review of Orphal, J., 2003. A critical review of the absorption cross-sections of O₃ and NO₂ in the ultraviolet and visible. *Journal of Photochemistry and Photobiology A Chemistry* 157, 185–209. See also the Spectral Atlas (Keller-Rudek, H., Moortgat, G.K., Sander, R., Sörensen, R., 2013. The MPI-Mainz UV/VIS spectral atlas of gaseous molecules of atmospheric interest. *Earth System Science Data* 5, 365–373. www.uv-vis-spectral-atlas-mainz.org) for a comprehensive set of data on the absorption cross section of ozone.

cross section, denoted by σ and usually given in units of cm² molecule^{−1}, is a measure of the ability of a molecule to absorb photons. The absorption cross sections can vary from zero to roughly 1×10^{-16} cm² molecule^{−1}. In some exceptional cases, for example in atoms, absorption cross sections can be much higher. An absorption cross section of $\sim 10^{-18}$ to 10^{-17} cm² molecule^{−1} is considered to be large. So, as shown in Figure 1, ozone is a strong absorber in the UV region and a weak absorber in the visible region. The extent to which the light is absorbed is given in terms of the absorption cross section, the concentration of the molecules (n , in molecule cm^{−3}), and the path length (l , in cm) by Beer–Lambert’s law, which states that

$$\frac{I}{I_0} = e^{-n\sigma l} \quad [3]$$

where I and I_0 are the intensities of transmitted and incident light, respectively.

The second quantity of interest is the ‘quantum yield’ for a given process, usually denoted by Φ , which is the fraction of molecules that have absorbed light that result in a specific process or lead to a specific product. The quantum yield for the dissociation of a molecule varies between 0 and 1. The quantum yield for the production of a photoproduct is also usually somewhere between 0 and 1, but can be greater than unity in some cases. For example, if O₃ photodissociates to give three atoms, the quantum yield

for O atoms is three, while the quantum yields for ozone loss is one.

The formation rate in the atmosphere (also called ‘photolysis frequency’) of O(¹D) from the photolysis of ozone is defined as follows

$$J(\text{O}^1\text{D}) = \int_{\lambda} \sigma(\lambda, T) \Phi(\lambda, T) F(\lambda) d\lambda \text{ in units of s}^{-1} \quad [4]$$

where $\sigma(\lambda, T)$ and $\Phi(\lambda, T)$ are the absorption cross section of ozone and the O(¹D) quantum yield at the photolysis wavelength λ and temperature T , and $F(\lambda)$ is the solar actinic flux in the units of photons cm^{−2} nm^{−1} s^{−1}.

Products of Ozone Photolysis

Photodissociation of ozone in the visible region, the Chappuis band, is a major contributor to the stratospheric production of O atoms in their electronic ground state (O(³P)). However, these atoms almost always combine with O₂ to form ozone with release of thermal energy (heat). Thus, the absorption of visible radiation by ozone converts light into heat and this conversion is particularly important in maintaining the temperature structure of the stratosphere.

In the first equation, $h\nu$ represents a photon of light of frequency ν and in the second equation M represents an inert atmospheric gas such as N_2 and O_2 . In most regions of the atmosphere, the interconversion between O and O_3 is so rapid that they are often treated together as one entity called 'odd oxygen,' denoted O_x .

The photodissociation of O_3 has been studied for many decades (Wayne, 1987). It has been shown that O_3 photodissociates to give an O atom and an O_2 molecule. The key questions are: (1) Does ozone dissociate every time it absorbs a visible or UV photon? (2) What energy states of O and O_2 are produced from ozone photodissociation? (3) How do the yields of the photofragments change with temperature, pressure, and wavelength? Clearly, the production of $O(^1D)$ or $O(^3P)$ leads to vastly different consequences in the atmosphere, as noted earlier. Understanding why these species are formed at the specific wavelengths is also of interest. From various studies that have been carried out to date, it appears that ozone always dissociates when it absorbs a visible or UV photon, at least at pressures encountered in the Earth's atmosphere. Therefore, we can assume that the quantum yield for ozone dissociation is unity. This is true at all atmospheric pressures and, hence, the quantum yields are independent of pressure. Because the excited ozone produced upon absorption of UV and visible radiation exists for only a very short time, $<10^{-13}$ s, the identity of the molecule that surrounds this ozone does not matter, as the excited state has no time to collide before it dissociates. In other words, the composition of the atmosphere does not change the quantum yield for the dissociation of ozone.

The energetic thresholds for the production of various products from the photodissociation of ozone are shown in Table 1. This table merely shows what is energetically possible at 298 K. However, the nature of the excited state of ozone produced upon light absorption determines which set of products is possible at a given wavelength and temperature. Since several different excited states can be created by absorption of light at one wavelength, it is possible to get multiple sets of products. These photochemical reaction pathways have been elucidated via experiments over the past few decades (Wayne, 1987; Matsumi and Kawasaki, 2003).

Table 1 Energetic and wavelength threshold for the production of various electronic states of O and O_2 in the photodissociation of ozone

Products	Threshold energy (kJ mol ⁻¹)	Threshold wavelength (nm)
$O(^3P) + O_2(^3\Sigma)$	106.6	1118.4
$O(^3P) + O_2(^1\Delta)$	199.1	599.2
$O(^3P) + O_2(^1\Sigma)$	263.5	452.6
$O(^1D) + O_2(^3\Sigma)$	296.1	402.8
$O(^1D) + O_2(^1\Delta)$	388.5	307.0
$O(^1D) + O_2(^1\Sigma)$	452.9	263.3
$O(^3P) + O(^3P) + O(^3P)$	605.1	197.1

Threshold energies and wavelengths are for 298 K and assume that ozone is in the ground vibrational state. $O_2(^3\Sigma)$ is the ground state of molecular oxygen, with the first and second excited states of O_2 being $O_2(^1\Delta)$ and $O_2(^1\Sigma)$, which lie 94.1 and 156.8 kJ mol⁻¹ above the ground state.

Formation of $O(^1D)$ via Ozone Photolysis in the Atmosphere

Over the past 35 years, the photodissociation of ozone has been carefully examined to quantify how much $O(^1D)$ is produced in the atmosphere subsequent to UV absorption by ozone. This examination was stimulated by the suggestion of Levy (1971) that OH radicals can indeed be formed in the lower atmosphere, where H_2O photolysis to produce OH is not possible. He suggested that the reactions involving the photolysis of ozone to produce $O(^1D)$ followed by the reaction of a fraction of the $O(^1D)$ with H_2O that produces OH to be a source of OH (eqn [1]).

The main atmospheric constituents, N_2 and O_2 , quench almost all the $O(^1D)$ to $O(^3P)$ in the atmosphere. We will first discuss the photochemistry in the UV region, i.e., below 400 nm in the Hartley (220–310 nm) and Huggins bands (310–370 nm), and then in the visible region, the Chappuis band (400–700 nm).

Because of absorption by overhead ozone, the actinic flux available for ozone photolysis in the lower stratosphere and the troposphere decreases very rapidly below ~ 330 nm. Stratospheric ozone acts as a UV shield by absorbing most of the biologically active UV radiation. Since light below ~ 290 nm essentially does not reach the lower stratosphere and the troposphere, the critical wavelengths for the photodissociation of ozone in this altitude region is restricted to ~ 290 – 350 nm. The upper limit for this wavelength range comes about because the absorption cross section of ozone in the Huggins bands becomes so small at, or beyond, 350 nm that, even with the increased solar actinic flux (by more than four orders of magnitude), the photodissociation of ozone becomes negligible. This is precisely the wavelength region where $O(^1D)$ production decreases from near-unity values around 305 nm to near-zero values around 350 nm, as shown in Figure 2. Therefore, the calculated atmospheric $O(^1D)$ production rate is very sensitive to the wavelength dependence of the quantum yield for its production in this wavelength range. It is also this region where the UV absorption cross sections of ozone $\sigma(O_3)$ and the quantum yields Φ for $O(^1D)$ production are highly sensitive to temperature. Thus, all the factors that together determine the $O(^1D)$ production rate are simultaneously changing rapidly with wavelength in this critical region. Therefore, accurate determinations of these parameters are thus crucial. Since the absorption cross section are reasonably well known and available light levels can be calculated, the uncertainty in photochemistry of ozone is the main concern for calculating the $O(^1D)$ production rate.

Quantum Yield for Formation of $O(^1D)$ in the Photolysis of Ozone

Early Quantum Yield Measurements

Until the mid-1990s, based on many previous data, it was assumed that the $O(^1D)$ production decreases monotonically from a near-unity value at ~ 290 nm to zero by ~ 310 nm. The threshold for the energetically allowed channel to produce $O(^1D)$ and $O_2(^1\Delta)$, the first electronically excited state of O_2 molecule, is ~ 307 nm for all ozone in the ground vibrational state (Table 1). However, one would expect the threshold to be shifted to a longer wavelength (~ 310 nm) because a fraction of the ozone

Figure 2 A representation of the various factors that determine the rate of $O(^1D)$ production in the atmosphere. The green line is the absorption cross section of ozone (note the logarithmic scale). The red curve is the current quantum yield (see [Figure 4](#) for recently determined values). The blue line is the approximate calculated solar flux at the surface for equinox, a solar zenith angle of 40° , US standard atmosphere conditions, an overhead ozone column of 300 DU, and a surface albedo of 5%.

molecules will have internal (extra) energy in the form of vibrational energy and hence increase the threshold wavelength.

It was assumed that the quantum mechanical electronic spin conservation rules would require the coproduct of $O(^1D)$ to be $O_2(^1\Delta)$ and that for $O(^3P)$ to be $O_2(^3\Sigma)$, since the upper state of ozone accessed by absorption is a singlet state formed via the strongly allowed transition from a singlet ground state.

The earliest measurements of $O(^1D)$ quantum yield in ozone photodissociation were those of [Jones and Wayne \(1970\)](#) as shown in [Figure 3](#). Their results agreed with the above expectation of zero quantum yields around 320 nm that increased to unity around 300 nm. Later studies of Moortgat and coworkers ([Arnold et al. \(1997\)](#); [Moortgat and Kudszus \(1978\)](#); [Moortgat and Warneck \(1975\)](#)) showed that the quantum yield changed with wavelengths above 305 nm to produce the shape shown in

Figure 3 Earliest measurement of the quantum yield for production of $O(^1D)$ in the photodissociation of O_3 by [Jones and Wayne \(1970\)](#) (blue curve). The other two curves are the determinations by Moortgat and coworkers at 298 K (red) and 230 K (green). Adopted from the data in the paper of Jones, I.T.N., Wayne, R.P., 1970. The photolysis of ozone by ultraviolet radiation, IV. The effect of photolysis wavelength on primary steps. *Proceedings of the Royal Society of London A* 319, 273–287 and Moortgat, G.K., Kudszus, E., 1978. Mathematical expression for the $O(^1D)$ quantum yield from the O_3 photolysis as temperature (230–320 K) and wavelength (295–320 nm). *Geophysical Research Letters* 5, 191–194.

[Figure 3](#). In these studies, which were state-of-the-art at that time, the measured quantum yields for $O(^1D)$ reached zero by 330 nm and this variation was not very sensitive to temperature in the wavelength range of 305–330 nm. Many other studies followed and were generally in agreement with this conclusion. The studies by Moortgat and coworkers were a major advancement over those of earlier studies. They had to use indirect methods since powerful lasers for photolysis were not yet available and direct detection of $O(^1D)$ was difficult, especially when the absorption cross sections and quantum yields were very low, for example, beyond 320 nm. Yet, these determinations of the $O(^1D)$ quantum yields enabled the calculation of $O(^1D)$, and hence of the OH radical, production rates in the atmosphere and firmly established Levi's mechanism for OH production in the atmosphere.

Presence of a 'Tail' in the $O(^1D)$ Quantum Yield

There were, however, some laboratory data that suggested the presence of a 'tail' in $O(^1D)$ quantum yield (i.e., a nonzero quantum yield) beyond the energetic threshold. [Adler-Golden et al. \(1982\)](#) had clearly pointed out that vibrationally excited ozone, which is naturally present in the atmosphere, could give $O(^1D)$ via the spin-allowed channel well beyond the 307 nm energetic threshold calculated for the ground state of ozone. Thus, the vibrational excitation of ozone decreased the energy barrier for $O(^1D)$ production and extended this photochemical process to longer wavelengths. [Michelsen et al. \(1994\)](#) showed that the effect of the vibrationally excited ozone in the atmosphere was to give nonzero quantum yields, which varied with temperature, beyond the thermodynamic limit of 307.0 nm (see [Table 1](#)). The quantum yield in this wavelength region from atmospheric ozone was expected to decrease with decreasing temperature because the fraction of vibrationally excited ozone molecule would decrease with temperature.

The introduction of improved direct $O(^1D)$ detection methods and availability of tunable laser light sources since the mid-1990s started a new period of intensive study. [Matsumi et al. \(2002\)](#) present an excellent survey of the direct and indirect techniques used for $O(^1D)$ atom detection. [Armerding et al.](#)

(1995), Talukdar et al. (1998), Bauer et al. (2000), and Silvente et al. (1997) introduced $O(^1D)$ detection by laser-induced fluorescence (LIF) to monitor OH products of $O(^1D)$ reactions. Takahashi et al. (1996b, 1998) and Taniguchi et al. (2000) applied direct VUV photolysis LIF for $O(^1D)$ detection at 115 nm and $O(^3P)$ at 130 nm. Chemical ionization combined with mass spectrometry has been used by Smith et al. (2000) to measure $O(^1D)$, while Hancock and coworkers (Ball et al. 1997; Denzer et al. 1997, 1998; Ravishankara et al. 1998) introduced direct resonance-enhanced multiphoton ionization. Very recently, Vranckx (2009) has used another chemiluminescence method to detect $O(^1D)$. All these techniques and measurements of the $O(^1D)$ quantum yield – with direct and indirect detection methods – showed clearly the existence of the ‘tail.’ Moreover, they showed that $O(^1D)$ is produced well beyond the 310 nm threshold proving that the quantum yield does not go to zero even at wavelengths as long as ~ 330 nm even when the temperature is low enough to eliminate the existence of a significant fraction of vibrationally excited ozone.

$O(^1D)$ Quantum Yield Determinations

The absolute quantum yield for $O(^1D)$ has been measured at various wavelengths between 300 and 350 nm in some studies while other studies have measured the quantum yields at various wavelengths relative to a benchmark wavelength. Here, we use 308.0 nm as the benchmark to place all measurements on an absolute scale.

Absolute $O(^1D)$ Quantum Yield at 308.0 nm

Overall, the dataset for the shape of the $\Phi(O(^1D), \lambda)$ fall-off curve at wavelengths between ~ 308 and ~ 340 nm is in reasonable

agreement but exact values as a function of wavelength and temperature differed considerably. Furthermore, the wavelength dependent quantum yield values of $\Phi(O(^1D), \lambda)$ were measured relative to different reference wavelengths. Therefore, a standard reference wavelength at 308.0 nm was established for the $O(^1D)$ quantum yield. Since the photolysis yield for O_3 on absorption of one photon is unity, and the threshold for $3O(^3P)$ is 197.1 nm at 298 K (Table 1), the amount of $O(^1D)$ produced can be compared with the total amount of oxygen atoms formed for an absolute determination. An absolute yield of $\Phi(O(^1D)) = 0.79 \pm 0.12$ at 308.0 nm, independent of temperature, has been measured by several groups using two different techniques. A more accurate value of $\Phi(O(^1D)) = 0.804 \pm 0.048$ was obtained at 308.0 nm by Takahashi et al. (2004), confirming the previous measurements. Here we normalize all the results to a $\Phi(O(^1D), 308.0 \text{ nm}) = 0.79$.

All previous relative $\Phi(O(^1D))$ measurements were put on an absolute scale by an independent group of principal investigators of these recent studies working in the area of ozone photodissociation. This panel conducted a rigorous evaluation of the experimental data for $O(^1D)$ production in the wavelength range 306–328 nm and temperature range 200–320 K (Matsumi et al., 2002). The quantum yield of eight studies were renormalized using $\Phi(O(^1D)) = 0.79$ at 308.0 nm and averaged to produce the $\Phi(O(^1D), \lambda)$ as a function of wavelength, as shown in Figure 4.

Temperature Dependence

All these recent data agree as to how the $O(^1D)$ quantum yield changes with wavelength and substantiate the existence of the temperature-dependent ‘tail’ and of the spin-forbidden photodissociation pathway. The renormalized data were used to obtain the best-fit parameters for the wavelength range

Figure 4 Wavelength dependence of the $O(^1D)$ quantum yields in the photolysis of O_3 at 298 K. The values reported by nine studies have been renormalized to a quantum yield of 0.79 at 308.0 nm. The best fit of these data is shown as the gray line. After Matsumi, Y., Comes, F.J., Hancock, G., Hofzumahaus, A., Hynes, A.J., Kawasaki, M., Ravishankara, A.R., 2002. Quantum yields for production of $O(^1D)$ in the ultraviolet photolysis of ozone: recommendation based on evaluation of laboratory data. *Journal of Geophysical Research* 107. <http://dx.doi.org/10.1029/2001JD000510>.

306–328 nm and the temperature range 200–320 K. Because of the large number of studies upon which the evaluation is based, the averaged 298 K data were given a larger weight in the fitting procedure than the data at other temperatures. The NASA/JPL panel (Sander et al., 2011) recommends the fitting expression derived by Matsumi et al. (2002), using three Gaussian terms and a constant term representing the spin-forbidden channel, for use in atmospheric modeling. Figure 5 shows the wavelength dependent $O(^1D)$ quantum yield at various temperatures in the range 205–321 K.

Physical Processes of $O(^1D)$ Formation

In the wavelength region of 290 to ~ 340 nm, the following processes are possible based on energetics (the threshold wavelengths are shown for 0 K):

The nonzero $O(^1D)$ yield beyond the threshold for spin-allowed channel (process [5a]) has been attributed by Takahashi et al. (1996a) to the existence of a previously unobserved spin-forbidden channel [5b] for $O(^1D)$ production, i.e., formation of $O(^1D) + O_2(^3\Sigma)$. The occurrence of the spin-forbidden photodissociation to produce $O(^1D)$ with a temperature-independent near constant quantum yield up to 335 nm is suggested by various studies. The process [5b] was reported

Figure 5 The quantum yield for $O(^1D)$ as a function of wavelength at a few temperatures. These are the values obtained from a detailed evaluation of the existing data by Matsumi, Y., Comes, F.J., Hancock, G., Hofzumahaus, A., Hynes, A.J., Kawasaki, M., Ravishankara, A.R., 2002. Quantum yields for production of $O(^1D)$ in the ultraviolet photolysis of ozone: recommendation based on evaluation of laboratory data. *Journal of Geophysical Research* 107. <http://dx.doi.org/10.1029/2001JD000510>.

to extend even to 375 nm by Bauer et al. (2000). Other spin-forbidden products in the photodissociation of ozone have also been observed, such as $O_2(^1\Delta)$ photofragments in the range 310–328 nm [5d] by Denzer et al. (1997, 1998) and Ravishankara et al. (1998), and $O_2(^1\Sigma)$ photofragments in the range 335–352 nm [5c] by O’Keeffe et al. (1998). Thus, it appears that the spin-forbidden channels are more prevalent than previously believed.

The observed $O(^1D)$ quantum yield wavelength dependence clearly shows that three processes occur. Matsumi et al. (2002) summarized the contributions of the three processes in Figure 6: (1) Ozone in the ground vibrational level absorbs light below ~ 310 nm to give $O(^1D)$ and $O_2(^1\Delta)$. This process [5a], which decreases very rapidly as the wavelength increases above the threshold, is the largest contributor to the rapid change in the quantum yield with wavelength and is not very sensitive to temperature (Region I). (2) Ozone present in vibrationally excited states photodissociates at wavelengths longer than 310 nm. It also contributes below 310 nm, but its contribution is not significant compared to the dissociation from the ground state. The vibrational energy of ozone allows $O(^1D)$ production beyond 310 nm, to approximately 320 nm, and is an allowed process. As the temperature is lowered, the contribution of this channel decreases as the population of vibrationally excited ozone decreases (Region II). (3) Ozone excited from its ground vibrational state photodissociates to $O(^1D) + O_2(^3\Sigma)$, a spin-forbidden process [5b]. The contribution of this channel, which is small but significant, appears to be essentially independent of temperature and wavelength (Region III).

Figure 6 Contributions made by the different O_3 photolysis channels to the $O(^1D)$ quantum yield. Region I corresponds to the $O(^1D)$ formed via process $O(^1D) + O_2(^1\Delta)$; region II (vertical hatching) represents the contribution of the hot band excitation of this process at 298 K, while region III (diagonal hatching) corresponds to the contribution of $O(^1D)$ via the spin-forbidden channel $O(^1D) + O_2(^3\Sigma)$. The solid lines are the recommended $O(^1D)$ quantum yield for 203, 253, and 298 K in the wavelength range 305–330 nm. Adapted from Matsumi, Y., Comes, F.J., Hancock, G., Hofzumahaus, A., Hynes, A.J., Kawasaki, M., Ravishankara, A.R., 2002. Quantum yields for production of $O(^1D)$ in the ultraviolet photolysis of ozone: recommendation based on evaluation of laboratory data. *Journal of Geophysical Research* 107. <http://dx.doi.org/10.1029/2001JD000510>.

Measurements of $O(^1D)$ Quantum Yield in the Region 305–375 nm

In some of the mentioned studies, it was observed that $\Phi(O(^1D), \lambda)$ does not drop to zero at wavelengths longer than 328 nm. The spin-forbidden channel leads to a temperature- and wavelength-independent yield of $O(^1D)$. Smith et al. (2000) reported a nearly constant $\Phi(O(^1D)) \sim 0.12$ between 328 and 338 nm, while Bauer et al. (2000) found a constant yield of 0.064 ± 0.006 up to 375 nm. The evaluation panel recommended a value $\Phi(O(^1D)) = 0.08 \pm 0.04$ independent of temperature up to 338 nm.

Since the $O(^1D)$ formation rate in the atmosphere at large solar angles is sensitive to the $O(^1D)$ quantum yield up to about 340 nm, and since the wavelength range 310–335 nm has large contribution to $O(^1D)$ production, further studies of the quantum yields in this region would be beneficial. Because of the very low absorption cross sections of ozone in this region, experimental measurements are very difficult. Beyond ~ 330 nm, the majority of the ozone dissociated to yield $O(^3P) + O_2(^3\Sigma)$, the spin-allowed channel [5e]. Currently, it is not clear if the small spin-forbidden $O(^1D)$ production [5b] channel extends to ~ 400 nm, the energetic threshold for this process (Table 1).

This motivated a recent study to examine the $O(^1D)$ yield over the wavelength range 311–333 nm using a novel technique for detection for both $O(^1D)$ and $O(^3P)$ based on CF_2 chemiluminescence (Vranckx, 2009). The results of this study match the evaluation given by Matsumi et al. (2002). They also confirmed the participation of the vibrational enhanced photolysis channel [5a] $O(^1D) + O_2(^1\Delta)$ up to 325 nm, and established the formation of a constant $O(^1D)$ quantum of $= 0.081$ above 325 nm from the spin-forbidden process [5b]

$O(^1D) + O_2(^3\Sigma)$. The results from the study by Vranckx are also shown in Figure 4. It can be seen that the new results match previous results and the current NASA/JPL recommendation (Sander et al., 2011).

Atmospheric Implications of the New $O(^1D)$ Quantum Yields

The significance of these changes in $O(^1D)$ quantum yields is very important to atmospheric calculations. One measure of this importance is the change in the rate of $O(^1D)$ production in the atmosphere as measured by the first-order rate coefficient for this process. Figure 7 illustrates the change in the calculated $O(^1D)$ production rate when the processes discussed above are included. There are many situations in the atmosphere where the available wavelengths are restricted to greater than 310 nm, where the importance of the ozone photodissociation via the excited ozone and the spin-forbidden channels become dominant. Such situations include high solar zenith angles and large overhead ozone columns, both common at high latitudes during late fall to early springtime. Of course, high solar zenith angles occur everyday at all sunlit locations at least for a short period.

Ozone Photochemistry in the Region 150–305 nm

Throughout the Hartley band continuum at wavelengths below 305 nm, ozone photolysis occurs via the two spin-allowed processes [5a] and [5e], and the quantum yield for $O(^1D)$ is large and close to unity. However, it appears that the quantum yield of $O(^1D)$ never reaches unity, that is, $O(^3P)$ is always

Figure 7 The impact of including the formation of $O(^1D)$ production at wavelengths longer than ~ 320 nm. The black curve on the left panel is the quantum yield for the formation of $O(^1D)$ as a function of wavelength that was used before the discovery of the tail and the spin forbidden channels. The red and green curves are the quantum yields for $O(^1D)$ at 298 and 200 K, based on the best evaluation. The inclusion of these quantum yields changes the $O(^1D)$ production rate from the black curve to the pink curve in the right panel. Adapted from Ravishankara, A.R., Hancock, G., Kawasaki, M., Matsumi, Y., 1998. Atmospheric photochemistry of ozone: surprises and recent lessons. *Science* 280, 60–61.

produced, at least down to 193 nm. The $O(^1D)$ quantum yield in the photolysis of O_3 was determined at 297 K in the wavelength range 230–308 nm by Takahashi et al. (2002) relative to $\Phi(O(^1D)) = 0.79$ at 308.0 nm as a reference. The $O(^1D)$ quantum was found to be almost independent of the photolysis wavelength over the Hartley band (~ 0.91). The results of this study are shown in Figure 8 together with the data of other previous reported studies at a few discrete wavelengths. In several follow-up studies in the range 193–225 nm, the $O(^1D)$ quantum yield was found to decrease from 0.90 ± 0.12 to 0.48 ± 0.03 at 193 nm (Nishida et al., 2004; Turnipseed et al., 1991). The earlier study of Taherian and Slanger (1985) shows that the $O(^1D)$ quantum yield continues to decrease with decreasing wavelength with a value of ~ 0.3 at 156 nm (This study also showed the formation of oxygen atoms in its second excited state, $O(^1S)$). The recent NASA/JPL panel recommended a value of $\Phi(O(^1D)) = 0.90$ in the range 220–305 nm independent of temperature.

The coproduct of $O(^3P)$ is assumed to be $O_2(^1\Sigma)$, with a large amount of internal and translational energy. Stranges et al. (1995) characterized the highly excited triplet states of O_2 , and additional channels corresponding to $O_2(^1\Delta)$ and $O_2(^1\Sigma)$ by the photolysis of O_3 at 193 nm. However, in the face of the prevalence of spin-forbidden processes at longer wavelengths, it may be useful to characterize the electronic state of O_2 that is produced in the range 200–300 nm. Sufficient work has not been done in this wavelength region to elucidate fully the quantum yield of $O(^1D)$. The wavelength region of 220–305 nm is not of major significance to the lower atmosphere because most light in this region is absorbed by ozone before it reaches the mid and lower stratosphere. Above ~ 40 km, O_2 photolysis starts to contribute significantly to $O(^1D)$ production and generation via ozone photolysis decreases in relative importance since the O_2 is so much more abundant than ozone.

Figure 8 Quantum yield values for the $O(^1D)$ formation in photolysis of ozone in the Hartley band as a function of photolysis wavelength. Original data obtained by various groups are plotted (see legend). The solid line represents the current NASA/JPL recommended value of 0.90. Formation of $O(^3P)$

Below 200 nm, where a new band of ozone appears, the photochemistry of ozone is not as well understood as in the 200–350 nm region. There are some indications that ozone photolysis in this region, specifically at 193 nm, can yield three oxygen atoms.

Production of three O atoms from ozone could be due to one of two processes: (1) the excited ozone molecule splits apart into three O atoms or (2) the excited atom splits apart into an O atom and an O_2 molecule that is sufficiently excited to decompose into two O atoms. If the production of three ground state O atoms in ozone photolysis is prevalent in this region, as pointed out by Turnipseed et al. (1991), photodissociation of O_3 can actually lead to ozone production.

Such ozone production will be, however, limited to high in the atmosphere because O_2 shields the lower levels from wavelengths less than 200 nm.

The identities of the electronic states of the products of the photodissociation of ozone in the Chappuis band have not been extensively studied. However, all the available data to date suggest that $O(^3P)$ is the primary product with a quantum yield of unity. It also appears that the coproduct of this $O(^3P)$ is $O_2(^3\Sigma)$, the ground electronic state of O_2 . This conclusion is based mostly on the observation that the quantum yield for the removal of ozone in the photolysis of pure ozone in the Chappuis band is close to two. If other electronic states of O_2 were produced, one would expect a larger quantum yield for the removal of ozone. Even though the flux of $O(^3P)$ produced by ozone photolysis in the visible is large and the abundance of $O(^3P)$ is orders of magnitude larger than that of $O(^1D)$, $O(^3P)$ does not play a major role in chemical transformations within the atmosphere. This is primarily because of the low reactivity of $O(^3P)$ compared to that of $O(^1D)$. However, visible photolysis of ozone to produce $O(^3P)$ followed by its reaction with O_2 to regenerate O_3 (the primary fate of $O(^3P)$ in the atmosphere) is a major pathway for the conversion of solar light to heat. It plays a significant role in determining the vertical temperature structure in the stratosphere.

Conclusions

The absorption cross sections and pathways for the dissociation of O_3 have been well established via experimental studies. The atmospheric importance of ozone and its dissociation pathways has been the primary driver for the large amount of experimental work that quantified absorption cross sections and quantum yields for various products. We have summarized the experimentally derived information in this article. Clearly,

the simple ozone molecule has a very complex photochemistry and this complexity profoundly affects the chemistry of the atmosphere. We just note that theoretical attempts to understand the photochemistry of ozone started decades back and there have been many theoretical studies carried out to date to understand ozone photodissociation. A recent article reviews the new theoretical investigations in the photodissociation of ozone in the four major absorption bands (Grebenshchikov et al., 2007). The complexity of ozone photodissociation has made it difficult to theoretically elucidate the dissociation processes and quantify their occurrence. Advancements in theoretical understanding would be beneficial for enabling predictions where experimental data are limited and extending our understanding to the photochemistry of other molecules.

Synopsis

Stratospheric ozone is depleted as a result of chemical loss caused by artificial chemicals. Maximum losses occur over the poles with the strongest loss in Antarctica (ozone hole). As a result of the Montreal Protocol, human-produced chemicals causing ozone depletion decline now in the atmosphere, so that a recovery of the ozone layer is expected. In the upper stratosphere (about 30–50 km), the previously observed decline has stopped since a few years, but an unequivocal detection of ozone recovery in other parts of the stratosphere is not possible yet.

Introduction

The phenomenon of depletion of the stratospheric ozone layer by human-produced chemicals has been dealt with in other parts of this Encyclopedia (*see Ozone Depletion and Related Topics: Ozone Depletion Potentials; Ozone as a UV Filter; Photochemistry of Ozone; Climate and Climate Change: Volcanoes: Role in Climate; Ozone Depletion and Related Topics: Surface Ozone (Human Health); Surface Ozone Effects on Vegetation*). Here, we deal with the recovery of the ozone layer – the reasoning behind the predictions that the ozone layer will recover to a state not exactly as it was prior to about 1980 (when the effects of ozone depletion clearly emerged) but to a state in which the threat of harmful ultraviolet radiation increases is no longer an environmental concern.

The subject of the recovery of the stratospheric ozone layer was dealt with in the most recent World Meteorological Organization (WMO)/United Nations Environment Programme (UNEP) Scientific Assessment of Ozone Depletion: 2010. Moreover, the reader is referred to Chapter 12.4 of the WMO/UNEP Scientific Assessment of Ozone Depletion: 1998 (*see Further Reading*) for an extensive discussion of stratospheric ozone recovery. We will summarize here why recovery is expected and discuss the models used to predict the course of recovery. Further, the measurements related to recovery of the ozone layer will be updated and the first signs of a recovery of the ozone layer will be discussed.

Ozone loss in the polar regions during spring is much more severe than the reduction that has occurred at midlatitudes since about 1980. This is related mainly to the fact that in order for chemical ozone destruction to proceed rapidly, very low temperatures and the presence of surfaces for heterogeneous chemistry are required. In most of the global stratosphere, temperatures are too high for rapid heterogeneous reactions of chlorine-bearing species. Conditions for rapid ozone depletion occur in polar winter and spring in association with very low temperatures and stratospheric aerosol and cloud particles together with the onset of springtime sunlight following the dark winter.

Shortly after the discovery of the Antarctic ozone hole in 1985, expeditions to Antarctica in 1986 and 1987 to determine the cause of the springtime ozone depletion resulted in considerable public awareness of the phenomenon. Even now, each austral spring (September–October) finds the Antarctic ozone hole in the news, with reports that either it was ‘not as bad’ as last year or that ‘it was worse than last year.’ In addition, expeditions to study Arctic ozone loss have demonstrated that major ozone loss may occur when Arctic springs are unusually cold. Indeed, the Arctic spring of 2011 showed unusually low temperatures until late in spring were observed, which resulted in severe ozone losses, reaching levels hitherto only observed in Antarctica (Manney et al., 2011).

These events have resulted in considerable confusion concerning the eventually expected outcome of this phenomenon. In actuality, the year-to-year fluctuations in the severity of the ozone hole have been relatively small in recent years, as can be seen in [Figure 1](#), where the total column ozone as measured at the South Pole during the later half of October and at the Halley station (75° S) in October are shown. Adequate sunlight for measurements of total ozone with the Dobson ozone spectrophotometer is available only after mid-October at the South Pole. Variations in the magnitude of Antarctic ozone loss since the last ~15 years have been dominated by variations in temperature and the dynamics of the polar vortex, in which the winter–spring ozone depletion process is confined; in particular, in 2002.

Although the Arctic stratosphere does not get as cold in winter as does the Antarctic stratosphere, substantial ozone loss occurs in cold Arctic springs. Arctic ozone loss is much more variable from year to year than in Antarctica, with little or no loss occurring in warm winters and in winters with a very early breakup of the vortex ([Figure 2](#)). The strongest Arctic ozone loss so far was observed in the extremely cold Arctic spring of 2011. The future of Arctic ozone depletion will depend on a number of factors, including climate change and, possibly, an artificial injection of sulfate particles into the stratosphere to counteract climate change (geoengineering), which is discussed.

At midlatitudes, ozone losses are much smaller. The smaller loss, together with large ozone fluctuations related to transport, makes the detection of midlatitude ozone loss more difficult than in the polar regions. Since midlatitude temperatures are not low enough for rapid heterogeneous reactions of

[†] Deceased.

Figure 1 Dobson spectrophotometer total column ozone measurements at South Pole station for the 15–31 October period and at Halley station (75° S) for October. Reliable data at South Pole are not available prior to 15 October owing to lack of sunlight for the measurement.

Figure 2 Minimum total ozone in the Arctic in March (calculated the minimum of daily average column ozone poleward of 63° S equivalent latitude). Years in which the polar vortex broke up before March are shown as open symbols. Updated from WMO, 2011. Scientific Assessment of Ozone Depletion: 2010. Global Ozone Research and Monitoring Project, Report No. 52. World Meteorological Organization. Figure courtesy of Jens-Uwe Grooß, Forschungszentrum Jülich.

chlorine-bearing species, and thus for widespread chlorine activation, chemical ozone loss rates are much lower than in the polar regions in spring. Following major volcanic eruptions, sulfuric acid aerosol droplets become important in the heterogeneous chemical process that leads to the enhanced destruction of ozone. **Figure 3** demonstrates the degree of ozone loss experienced across midlatitudes of the United States and shows how the fluctuations related to transport rival the losses experienced since 1980. Enhancement in ozone loss in 1992–93 is believed to be related to the stratospheric aerosol injected into the stratosphere by the eruption of Pinatubo in June 1991.

Global measurements and projected future abundances of the chlorine- and bromine-bearing gases believed responsible for most of the ozone depletion (referred to as ozone-depleting substances (ODSs)) are shown in **Figure 4**. These data indicate

that the combined equivalent effective stratospheric chlorine (EESC) abundance (EESC is a measure of the stratospheric halogen loading and its potential for ozone depletion and is calculated from the surface abundances of chlorine- and bromine-bearing ODS) peaked in the stratosphere in the late 1990s (several years after the peak loading of ODSs in the troposphere).

Thus, there is no reason to expect the Antarctic ozone hole or global ozone depletion to become significantly worse than at present. However, recovery of EESC and thus of the ozone layer to pre-1980 levels is not expected until the middle of the twenty-first century. Model predictions of climate change suggest that climate change should accelerate ozone recovery (in particular in the upper stratosphere) because climate change leads to lower stratospheric temperatures, which cause

Figure 3 Monthly average total column ozone deviations from the pre-1979 mean at four Dobson spectrophotometer stations across midlatitudes of the United States. The large reduction in 1992–93 is partially related to the Pinatubo volcanic eruption.

gas phase catalytic ozone loss cycles to proceed slower. In the Arctic, where a cooler stratosphere would enhance heterogeneous processing and exacerbate ozone depletion, climate change could delay ozone recovery. Major volcanic eruptions, which supply aerosol particles to the stratosphere, aid the heterogeneous chemistry of halogen ozone loss and will cause a delay in ozone recovery. Clearly, the road to recovery will not be smooth, but it appears that the remedy has been found and it is likely that the phenomenon of stratospheric ozone depletion will not get substantially worse than at present. But how long will the recovery of the ozone layer take?

Ozone Recovery Defined

When speaking about ‘ozone recovery’ here, we are concerned with the way the atmosphere responds to a reduction of the stratospheric halogen loading as a result of the Montreal Protocol and its amendments and adjustments. The first stage of ozone layer recovery is defined (WMO, 2011) as a slowing of ozone decline (i.e., a cessation in the worsening of ozone depletion), identified as the occurrence of a statistically significant reduction in the rate of ozone decline due to changing EESC, i.e., due to changing halogen loading. EESC values are represented as a weighted sum of reactive chlorine and bromine in the stratosphere, accounting for the greater effectiveness of bromine in destroying ozone and thus allowing an estimate how the potential of ODSs to destroy ozone varies over time.

This first stage is observed in the upper stratosphere since about the past decade. Ozone abundances in midlatitudes and in Antarctic spring have similarly ceased to decline since about a decade (Figures 1 and 3), but an unequivocal attribution to changes in the stratospheric halogen loading is difficult. The second stage of ozone recovery is defined as the onset of ozone increases and is identified as the occurrence of statistically significant increases in ozone above the previous minimum

values caused by declining EESC (WMO, 2011). The unambiguous detection of such a recovery is difficult because of the requirement to detect a statistically significant ozone increase, above natural variability, that is occurring slowly over a long period of time. Measurement stability and comparability between multiple instruments over a 20-year or longer period is thus required to detect recovery. These observations could be further confused by occasional volcanic eruptions that will cause ozone depletion to increase for 2–3 years during which the aerosol particles from the eruption slowly fall out of the stratosphere. At the 40-km region, where the chemistry-affecting ozone is relatively simple and volcanic effects are absent, recovery might be observable most easily. However, as ozone in this region contributes only a few percent to the total column, recovery at 40 km should not be interpreted as evidence for the recovery of the global ozone layer. Observation of ozone recovery is important because it can show that the implementation of regulations on ODSs, established by the Montreal Protocol and its amendments and adjustments, was an effective course to follow.

Modeling Ozone Recovery

Projections of future levels of stratospheric ozone are based on the results of three-dimensional chemistry climate models (CCMs) that allow a realistic description of the polar wind system (polar vortex) and that contain a comprehensive representation of stratospheric heterogeneous and gas-phase chemistry. Further, equivalent stratospheric chlorine (ESC) values are predicted in CCMs describing the potential of ODSs to destroy ozone. While both EESC and ESC are designed as a measure of essentially the same quantity, ESC may be calculated directly from models as a function of altitude, latitude, longitude, and time. For the purposes of this general discussion of ozone recovery, EESC and ESC are essentially equivalent. The range of total ozone changes and the range of changes in ESC since 1960

Figure 4 Measurements and projected future abundances of global chlorine- and bromine-bearing compounds that are included in the EESC calculation shown at the top left panel of the figure. Taken from WMO, 2011. Scientific Assessment of Ozone Depletion: 2010. Global Ozone Research and Monitoring Project, Report No. 52. World Meteorological Organization.

as derived from a variety of CCMs is shown in Figure 5. Comparison of model results simulating recent ozone changes with observations increases the confidence in projections of future stratospheric ozone, although, of course, there remain sources of uncertainties in CCM simulations.

Current CCM simulations predict that global annually averaged total column ozone returns to 1980 levels before the middle of the century, which is earlier than when the stratospheric halogen loading returns to 1980 levels (Figure 5). This accelerated recovery is driven by changes in climate, in particular decreasing stratospheric temperatures. Simulated changes in tropical total column ozone between 1960 and 2100 are generally small, but 2100 tropical ozone is predicted to be slightly lower than that in 1960. For the midlatitudes, CCMs predict a different development in the two hemispheres. In the northern midlatitudes, the models predict a return of annually averaged total ozone values to 1980 values between 2015 and 2030, while for Southern Hemisphere midlatitudes the return to 1980 values is predicted to occur between 2030 and 2040.

The difference between southern and northern midlatitudes is linked to a simulated strengthening of the poleward transport of ozone in the Northern Hemisphere and the impact of Antarctic ozone loss in the Southern Hemisphere. Spring total ozone values in the Arctic are projected to return to 1980 values two to three decades before the polar halogen loading returns to 1980 levels and to exceed 1980 levels thereafter. As CCMs generally underestimate the Arctic ozone loss, however, there is the possibility that the predicted return is too early. The latest time for recovery to 1980 conditions is projected for the Antarctic, namely recovery to 1980 conditions after mid-century. However, also in the Antarctic, ozone is predicted to return to 1980 conditions before the stratospheric halogen loading in this region returns to 1980 levels (Figure 5).

All the models depend on halogen levels declining as prescribed by the amended and adjusted Montreal Protocol. This includes future replacement of presently unregulated hydrofluorocarbons, halons, and other bromine-bearing compounds such as methyl bromide. If the emissions of these compounds

Figure 5 Long-term changes in total ozone and ESC. Values shown here are deduced from the simulations of CCMs that take into account the effects of ODSs and climate change on stratospheric ozone. Taken from WMO, 2011. Scientific Assessment of Ozone Depletion: 2010. Global Ozone Research and Monitoring Project, Report No. 52. World Meteorological Organization.

do not decline as prescribed by the Protocol, because of continued production and/or emission in developing countries who were provided special dispensations in the Protocol, then the predictions of recovery will, of course, not be accurate.

Observing the Recovery

The long-term variability of stratospheric ozone is generally estimated using multiregression statistical models that quantify the relationship between ozone and a variety of different explanatory variables describing both natural and anthropogenic forcings. Important examples for the natural forcings are the annual cycle of ozone, the 11-year solar cycle, the

quasi-biennial oscillation (QBO), and the volcanic effects. These forcings are extracted from the long-term time series simultaneously with trend components representing the effect of ODSs on ozone. The EESC is commonly used as the proxy representing the ODS effect in statistical models and different statistical techniques are used to test the statistical significance of the EESC-related terms (WMO, 2011).

Upper Stratosphere

In the upper stratosphere, a region where ozone changes are closely controlled by changes in EESC, the first stage of recovery has been reached, namely a statistically significant deviation of ozone from the previously observed linear decline. Until the

late 1990s, upper stratospheric ozone in midlatitudes declined by several percent per decade, but since then, the steep decline has ceased and ozone levels have increased by about 2.5% until 2011 (Figure 6; WMO, 2011). Upper stratospheric ozone is affected by parameters other than the change of ODSs, in particular by changing upper stratospheric temperatures and methane abundances. However, the good agreement of observed ozone decline between 1980 and the late 1990s with CCM simulations provides evidence that increases in ODSs over this period are responsible for the observed behavior (WMO, 2011). Likewise, the good fit of the observed ozone anomalies by EESC after the most important natural sources of ozone variability have been removed, provides strong evidence that the slowing of the upper stratospheric ozone decline can be attributed to the changes in ODSs.

Midlatitude Lower Stratosphere

At midlatitudes, unequivocal detection of ozone recovery is difficult. Here, the signal of ODS-driven ozone change is small

Figure 6 Ozone anomalies above the southern midlatitude station Lauder (New Zealand) averaged over the altitude range from 35 to 45 km after subtraction of the estimated QBO and solar cycle effect. For the satellite experiments Stratospheric Aerosol and Gas Experiment (SAGE), Solar Backscatter Ultraviolet Instrument (SBUV), and Halogen Occultation Experiment (HALOE), zonal mean data are shown. The underlaid thick gray line is the average anomaly record. The gray trend line gives the 1979–96 linear trend of the average record at each station, extrapolated after 1996. Natural variability due to the QBO and solar cycle is removed. Based on Steinbrecht et al. *Journal of Geophysical Research* 11, D10308, doi:10.1029/2005JD006454; figure courtesy of Wolfgang Steinbrecht, Deutscher Wetterdienst.

compared to natural variability, which makes difficult the detection of an ozone increase. However, observations show that total ozone in the midlatitudes (30–60°) of both hemispheres have remained at the same level for the period 1996–2009; namely 6 and 3.5% below the 1964–80 average for the Southern and Northern Hemispheres, respectively. The observed ozone decline in the lower stratosphere (20–25 km) between 1980 and 1996 is about 7% in both hemispheres. For the period 1996–2009, no statistically significant change is observed in the lower stratosphere in the Southern Hemisphere and a small increase by about 2.5% in the Northern Hemisphere (WMO, 2011).

Antarctica

In recent years, ozone has been totally destroyed in the heart of the ozone hole region at 15–20 km, which means that, in these regions, concentrations of active chlorine are greater than is required to destroy all the ozone available. Thus, this region is not expected to be an early indicator of the beginning of ozone recovery. However, at both the horizontal and vertical boundaries of the ozone hole region ozone loss is not saturated and thus in these regions there is an opportunity for detection of the beginning of recovery.

The horizontal extent of the ozone hole can best be observed by nadir-viewing satellite instruments, which detect total column ozone. It has been customary to use the 220 Dobson unit (DU) contour to define the outer boundary of the springtime Antarctic ozone hole as this is the value at which a steep gradient in ozone exists with substantial depletion internal and minimal depletion external to the 220 DU contour. Figure 7 shows the magnitude of the area interior to this contour, averaged for the springtime period from 9 September to 13 October, as a function of time since regular satellite measurements began in 1979. Since the early 1990s, this parameter has been in the range of $22 (\pm 2) \times 10^6 \text{ km}^2$. This is equivalent to the area poleward of about 66° S latitude. All but the tip of the Antarctic Peninsula lies internal to this area, so that the ozone hole defined in this manner covers essentially all of Antarctica.

At the boundary of the depletion region, stratospheric temperatures are not as low as internal to the boundary and thus the heterogeneous chemistry, which is responsible for chlorine activation, does not proceed as readily. Thus, assuming that temperatures will not change substantially with time, the area enclosed by the springtime 220 DU contour at maximum depletion could be a sensitive indicator of the beginning of ozone recovery in Antarctica. Here, dynamically induced variability must be discriminated from the change of ozone loss driven by reductions in ODSs. The most notable example of dynamically induced changes in the area enclosed by the 220 DU contour is the year 2002 (Figure 7), when a sudden stratospheric warming occurred in the Antarctic stratosphere.

The vertical extent of the ozone hole can be observed with balloon-borne instruments and has been monitored annually since 1986 at the South Pole. Figure 8 shows vertical ozone profiles measured at the South Pole during the ozone hole maximum depletion at the beginning of the current continuous measurement period in 1986 and during the ozone hole period

Figure 7 Geographical area of the 220 DU contour over Antarctica between 9 September and 13 October from Total Ozone Mapping Spectrometer (TOMS) satellite data. Red line indicates the area of the Antarctic continent. Figure courtesy of Paul Newman, NASA Goddard Space Flight Center.

in 2000. These profiles are compared to profiles measured at the South Pole prior to the advent of the ozone hole phenomenon during the 1967–71 period. The progression toward total ozone destruction in the 15- to 20-km region is clear. It also is clear that ozone depletion has progressed to higher altitudes during the 1986–2000 period, with a sharp top to the ozone hole at about 21 km in 1986 and about 24 km in 2000. Barring major temperature trends in this region, a decline in the top of the ozone hole would be an indicator of ozone recovery in Antarctica. However, near complete removal of ozone up to altitudes of 21 km has been observed in recent years and no observations of a decline in altitude of the top of the ozone hole have been reported (WMO, 2011; Hofmann et al., 2009).

Another parameter that will be sensitive to a decay of the stratospheric halogen loading is the rate of ozone loss in the main ozone loss region (14–21 km) during September, the period when ozone is declining rapidly (Figure 9). Pre-1990 values were in the range of 2.4 DU per day. In recent years, the value has been about 3 DU per day with large year-to-year variations, but no definitive signs of ozone recovery (Hofmann et al., 2009).

Arctic

The detection of the recovery of Arctic springtime ozone loss is expected to be more difficult than elsewhere in the stratosphere because models suggest that strong ozone losses in the Arctic are possible for many years owing to the more dynamic situation in the Arctic compared to the Antarctic (WMO, 2011). The interannual variability in the degree of springtime Arctic ozone depletion is much too large to allow any simple observations of the beginning of recovery of the Arctic ozone layer. Indeed, in March 2011, ozone concentrations in the Arctic stratosphere were the lowest ever recorded and ozone loss was

Figure 8 Ozone vertical profiles obtained with balloon-borne ozone-sondes at South Pole Station at the time of maximum ozone depletion in spring. Shown are profiles for the years 1986 (when continuous measurements began) and 2000. The recent measurements are compared to those made during the 1967–71 period.

comparable to that regularly observed in the Antarctic (Figure 2; Manney et al., 2011).

Summary and Conclusions

In the upper stratosphere, the first stage of recovery has been reached, namely a statistically significant deviation of ozone from the previously observed linear decline due to changing halogen loading. Ozone abundances in midlatitudes and in Antarctic spring have similarly ceased to decline since about a decade, but an unequivocal attribution to changes in the stratospheric halogen loading is difficult. The observed ozone decline in the lower stratosphere (20–25 km) between 1980 and 1996 is about 7% in both hemispheres and a small increase by about 2.5% is observed in the Northern Hemisphere thereafter.

There are different diagnostics that allow the detection of recovery of stratospheric ozone in Antarctic spring: the area of the 220 DU contour in late September/early October, the vertical extent of the area of extreme ozone depletion, and the rate of ozone loss (in DU per day) in September. All these measures show a certain natural variability and a cessation of ozone decline since more than a decade, but no clear signs of recovery caused by a reduction of the stratospheric halogen loading. Arctic ozone loss is very variable from year to year and the lowest ever recorded ozone concentrations occurred in March 2011.

A substantial recovery of the stratospheric ozone layer due to a reduction of the stratospheric halogen loading is projected by model simulations, but the resulting changes in ozone will depend strongly on geographical region. Simulated changes in tropical total column ozone between 1960 and 2100 are small. In the midlatitudes, the models predict a return of annually averaged total ozone values to 1980 values between 2015

and 2030 and in 2030–40, in the Northern and Southern Hemispheres, respectively. Spring total ozone values in the Arctic are projected to return to 1980 values in about 2040, two to three decades before the polar halogen loading returns to 1980 levels and to exceed 1980 levels thereafter. For the Antarctic, recovery to 1980 conditions is predicted to occur after midcentury.

However, the atmosphere – because of climate change – will develop into a different state than in 1980 over the course of the century, i.e., over the time period when ozone recovery will occur. Thus, the ozone layer in 2100 will have recovered from the effects of ODSs but, due to climate change, will be in a different state than it was in 1960 when the effects of ODSs on the ozone layer were not yet noticeable.

Surface Ozone Effects on Vegetation

M Ashmore, University of York, York, UK

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Current concentrations of surface ozone in many parts of the world can reduce crop yields, impair forest growth, and change plant species composition. Predicted increases in northern hemispheric background ozone concentrations are likely to increase these impacts over the first half of this century. Ozone effects on vegetation are modified by climate and CO₂ concentrations, while ozone itself can change ecosystem carbon budgets. For these reasons, surface ozone needs to be considered as an important element of global environmental change over this century.

Introduction

The effects of surface ozone on vegetation were first demonstrated in the Los Angeles Basin in the 1950s. Since then, extensive field and experimental research has demonstrated the wider impacts of ozone on crops and forests, especially in North America and western Europe. Surface ozone is now a global problem, with evidence of a trend of rising background northern hemispheric concentrations and increasing evidence of the impacts of ozone on vegetation in Asia, Africa, and Latin America. During a photochemical smog episode, a range of chemical species is formed, but there is little doubt that ozone is by far the most important of these in terms of effects on vegetation. Although evidence exists of the effects of other oxidants, such as peroxyacetyl nitrate and hydrogen peroxide, on vegetation, these are of minor significance compared with effects of ozone.

It is important to emphasize that ozone is just one environmental factor influencing vegetation, and that there are important interactions between ozone and climatic factors, soil conditions, and pests and diseases. Thus, any assessment of its impact on vegetation needs to consider the pollutant in the wider environmental context. Hence, assessment of ozone impacts on vegetation in different regions of the planet, and of the potential impact of the projected increases in background surface ozone concentrations during this century, must consider interactions with varying climatic conditions.

This article aims to provide an overview of surface ozone effects on vegetation. The first three sections provide an overview of methods of investigation, of the key mechanisms of damage, and of the relationships between ozone exposure and plant response. This is followed by two sections that provide more specific information about the two key impacts of surface ozone – on food production and on ecosystem services. This article concludes with consideration of possible future impacts of ozone, providing a global perspective and considering interactions with other components of global environmental change.

Methods of Assessing Ozone Impacts on Vegetation

A variety of methods have been used to study the impacts of ozone on vegetation, ranging from controlled laboratory chambers, which clearly link cause and effect but do so under

highly unrealistic conditions, through to field observations, which provide no certainty about the link between cause and effect. The most important source of information on the impacts of ozone on crop yield has been the use of exposure chambers in the field, in which ozone exposures can be modified and controlled, either by filtration of ambient pollutants or by the addition of ozone in temporal patterns that simulate ambient concentration profiles. The most commonly used type of chamber, the open-top chamber, provides microclimatic conditions that are comparable, but not identical to, those outside. [Figure 1](#) shows one such facility, in which different ozone treatments can be assigned to replicate chambers.

However, open-top chambers do modify the microclimate, for example, by increasing air and soil temperatures. They also significantly change the interactions between plants, insects, and fungal pathogens, while their size prevents their use for large tree species. One alternative method is the use of open-air fumigation systems, in which ozone is released over outdoor plots; this allows multiyear exposure of ecosystems under unmodified climatic conditions, the opportunity to study interactions between ozone exposure and extreme stress events such as storms, and realistic interactions with pest and disease organisms. [Figure 2](#) shows an example of such experiment in a field of soybean; ozone is released from different points within the ring depending on the wind direction, and replicate rings (not shown in [Figure 2](#)) can be assigned to different ozone treatments. However, such systems can only be used to examine the effects of increasing ozone concentrations above background, and they cannot be used to assess the effects of reducing ozone exposures. For crop species, ozone-protectant chemicals such as ethylene diurea (EDU) have also proved an effective means of identifying the effects of ambient ozone exposure.

There are enormous technical and logistical challenges and costs to exposing more mature trees to ozone over long periods of time under field conditions. However, two studies have done so in recent years, and have provided important new insights into the long-term effects of ozone exposure. The first of these (the AspenFACE field fumigation study in the northern US) applied elevated ozone and elevated CO₂ concentrations for a period of over a decade to communities of three important North American trees – aspen, birch, and maple – that were grown from seedlings. [Figure 3](#) provides an aerial photograph of this experiment, showing rings that have been assigned to different ozone and CO₂ concentrations. The second of these studies, based in the Kranzberg forest, in Germany, applied

Figure 1 Overview of the University of Newcastle open-top chamber facility at Close House, west of Newcastle-upon-Tyne, UK. The 16 open-top chambers are assigned to different controlled ozone treatments, depending on experimental objectives.

Figure 2 Overview of the University of Illinois SoyFACE experimental site, situated near Urbana, Illinois, US. ozone for 8 years to a mature mixed spruce and beech canopy that was planted about 60 years ago.

The limited duration of any chamber or field release experiment means that field observations may be the only feasible way of assessing the long-term impacts of ozone over decades. Indeed, field observations have played an important role in assessment of ozone effects on vegetation, especially where concentrations are high enough to produce characteristic visible symptoms of injury. However, spatial and temporal associations between plant response and ozone

exposure are much more difficult to demonstrate in regions with lower concentrations, because gradients in ozone exposure are often confounded with gradients in climatic and other factors.

Mechanisms of Impact

Ozone has impacts at different levels of organization, from the cellular to individual organs and plants, through to plant

Figure 3 Aerial view of the AspenFACE experimental site, situated at the Harshaw Experimental Forest near Rhinelander, Wisconsin, US. Each ring is assigned to a different controlled ozone and CO₂ treatment. Image taken from <http://aspenface.mtu.edu>.

communities and ecosystems. The effects of surface ozone can be conceptualized as having four stages:

1. Ozone is transferred from the boundary layer of the atmosphere to sites of damage within the leaf. There is little evidence that ozone deposition to external plant surfaces or to soil surfaces has any adverse effect; rather it is the flux of ozone through the stomatal pores, which regulate the exchange of gases between the atmosphere and the intercellular spaces within the leaf that is important. However, direct effects of ozone, not mediated through damage within the leaf, may occur on reproductive structures (e.g., pollen, flowers, and fruits).
2. Ozone causes damage and physiological changes within the leaf. The primary site of damage is thought to be the cell membrane, either directly due to ozone or indirectly due to secondary radical species formed by reactions with organic molecules within the leaf. At high concentrations, damage to the cell membrane induced by short-term exposure to ozone can cause cell collapse, leading to visible leaf injury. The most important long-term effect of ozone exposure within the leaf is a reduction in net CO₂ fixation as a result of both reduced photosynthetic activity and the increased rates of respiration, which are associated with maintenance and repair of damaged tissue.
3. Effects of ozone within the leaf have a range of other effects within the plant. Most importantly, ozone often reduces the translocation of assimilates to other parts of the plant, such as the roots and grains. The rate of production of new leaves is accelerated in some species in response to ozone stress, thus allowing the maintenance of plant growth rates, but

this is often at the expense of assimilate allocation to, and growth of, the root system and of storage organs. Ozone also accelerates the rate of leaf senescence, which in turn reduces the period of leaf growth with a positive carbon balance. The reduced carbon assimilation typically leads to reduced growth rates. Whether these in turn lead to reduced yields of agricultural or forest crops will depend on the allocation of assimilates to the harvested part of the plant, compared with other organs.

4. Effects of ozone within the plant have a wider range of ecological implications. These include effects on species composition and diversity, biogeochemical cycles, soil chemistry, and soil biology. Some of these effects are a direct consequence of the reduced photosynthesis and carbon assimilation in the leaf, but other mechanisms, such as interference with hormonal signaling by ozone, are also important. To provide one example of the range of effects that might occur within a simple experimental ecosystem, a study of a constructed meadow in Finland reported that ozone caused visible leaf injury, delayed the onset of spring growth, reduced leaf and root growth, delayed flowering, reduced the number of berries, reduced rust infection of the leaves, reduced nitrogen levels in the soil, reduced emissions of carbon dioxide (CO₂) and nitrous oxide from the soils, and reduced the microbial biomass in the soil.

The extent to which ozone entry into the leaf can lead to adverse effects on plant growth and yield depends on a range of defense and compensatory mechanisms. Within the leaf, antioxidant systems can reduce the impact of ozone. In particular, the levels of ascorbate, and other antioxidants, in the cell wall

may be critical in reducing the flux of molecules of ozone or secondary free radicals to sites of damage in the cell membrane. There is also clear evidence that exposure to ozone can result in upregulation of antioxidant systems in the plant through effects on gene expression.

The effect of a given ozone concentration is not fixed, but depends on a wider range of factors, which can be grouped into two broad categories. The first category is external factors, such as climate, soil type, and CO₂ concentration, which modify the responses of vegetation to ozone. As examples of the interactions with climate:

- Severe visible injury to sensitive species is most often found in periods when high ozone levels are associated with high atmospheric humidity, enhancing the uptake of ozone into the leaf.
- The effect of ozone on wood production and stem growth is lower on soils with a lower water-holding capacity, where drought conditions are more frequent, and greater in moist years than in dry years.
- Most plant species show little injury if exposed to ozone in the dark, when stomata are closed and there is little flux of ozone into the leaves, but in those species, which do retain open stomata at night, ozone damage may be greater, because of the lower antioxidant capacity within the leaf in the dark.

The second category is internal factors. Physiological, anatomical, and biochemical factors that vary between, and within, plant species, strongly influence the size of any impacts of ozone. It is long established that there is a large variation between species in their sensitivity to ozone. There is also considerable genetic variation in sensitivity within species, and gene loci associated with an increased tolerance of ozone stress have been identified. For crop species, the difference in sensitivity between cultivars may reflect inadvertent selection in the breeding process, although there is little evidence that modern crop cultivars, bred under greater ozone concentrations, are more tolerant of ozone. Indeed, some data suggest the opposite; for example, that modern wheat cultivars are more sensitive than those bred earlier in the twentieth century, possibly because characters that are associated with higher yield potentials are also associated with higher ozone sensitivity. Outside the agronomic environment, there is evidence that natural selection is operating to favor more ozone-tolerant genotypes in areas with higher ozone exposures.

Exposure-Response Relationships

While the mechanisms leading to adverse impacts of surface ozone on vegetation can be described qualitatively, policy assessments aim to quantify the size of the regional impacts of ozone, and the benefits of measures to reduce precursor emissions. This has typically involved an empirical approach, defining the relationships between ozone exposure and a limited range of measures of plant response related to plant growth or yield. A major issue in defining such exposure-response relationships for the cumulative effects of ozone over one or more growing seasons is the method used to summarize the seasonal ozone exposure. Different exposure

indices have been devised, describing different components of the seasonal ozone exposure, often giving higher weights to periods with higher concentrations, which are assumed to have a greater biological impact.

For annual crops, the main approach has been to fit statistical relationships between seasonal ozone exposure and final crop yield, based on experimental data, typically derived using open-top chambers. The first national program to determine exposure-response relationships for crops was the US National Crop Loss Assessment Network, which was established in the late 1970s and examined 10 crops, representing 85% of the cropped area of the United States. The experiments involved a range of ozone concentrations to generate relationships between ozone exposure and crop yield. Ozone exposure was expressed as the seasonal mean ozone concentration during either 7 or 12 h during the day. For a seasonal 7-h mean ozone concentration of 50 ppb, compared with a baseline of 20–25 ppb, estimated yield reductions for the most sensitive crops, such as soybean and cotton, exceeded 10%; for winter wheat they were slightly under 10%; and for the most tolerant crops, such as rice, barley, and sorghum, they were below 5%.

In western Europe, a similar experimental approach was applied to a smaller number of crops. A new cumulative seasonal ozone exposure index was developed, termed the AOT40, which sums the positive differences between hourly mean ozone concentrations and 40 ppb during all daylight hours over the growing season. The use of this index allowed a common linear exposure-response relationship to be fitted to spring wheat data from experimental studies in six different countries, with a 10% yield loss corresponding to an AOT40 value of about 5000 ppb h.

However, caution is needed in interpreting the exposure-response relationships derived from such experiments. In open-top chamber exposure-response experiments, ozone is added simultaneously in all treatments under the same climatic conditions. In contrast, when the impacts of ozone in different locations are compared, for example, across the continent of Europe, the very different climates may modify the impacts of ozone. For example, in the hotter and drier climates of southern Europe, the same ozone exposure may have less effect than under the cool moist climate of Scandinavia. Hence, although the highest ozone concentrations have the greatest impact under experimental conditions, under field conditions it is not necessarily the highest ozone concentrations that are most significant.

One reason for this is that highest ozone concentrations tend to occur under meteorological conditions that limit ozone flux through the stomata into the leaf. Since ozone flux from the atmospheric boundary layer into the leaf is a critical factor for adverse effects on vegetation, environmental factors that influence this flux may modify ozone impacts. Under most conditions, the most important factor controlling ozone flux is the stomatal conductance of the plant canopy; thus, high vapor pressure deficits or high soil moisture deficits, which are often associated with high ozone concentrations, tend to reduce ozone impacts.

Accordingly, rather than relate plant response to external ozone concentrations or exposure indices, it is mechanistically preferable to use the estimated flux of ozone into the leaf. There

is now a significant body of evidence, both statistical and biological, that an index based on the modeled accumulated seasonal O_3 flux through the plant stomata is better related to effects of O_3 on crop yield and forest growth than one based on external concentrations. Use of a flux-based index gives a very different spatial distribution of risk than does use of exposure-based indices, and evidence suggests that a flux-based evaluation is a better representation of the spatial distribution of impacts on vegetation across Europe. Flux-based dose-response relationships have now been developed for some of the most important environmental effects of O_3 – on crop yields, on carbon storage in forest trees, and on the food quality of pasture for grazing animals – and have been applied to assess the benefits of precursor emission reductions across Europe.

Effects on Food Production

Visible leaf injury to crop species has been reported in the field on many occasions since the first confirmed reports in the late 1950s in the United States. A list of crop species for which documented evidence of visible injury in the field following episodes of high ozone concentrations has been obtained in Europe includes beans, beetroot, chicory, clover, clementine, courgette, grapevine, maize, oats, onion, parsley, peach, peanut, potato, radish, soybean, tobacco, tomato, watermelon, and wheat. This indicates the wide range of crop species that can be affected. [Figure 4](#) provides an illustration of some of these typical symptoms of visible injury. In some of these cases, the appearance of visible injury on leaves would directly reduce the economic value of the crop, but in most cases it is the long-term effect on the yield of the harvested part of the crop that is important. Visible leaf injury to shrub and forest species has also been reported in the field in Europe and North America, especially on sensitive deciduous species, such as poplar, ash, and black cherry.

There have been many experimental studies to demonstrate the significant impact of ozone exposures on crop yield in western Europe and North America. The exposure-response studies described in the previous section have been integrated with databases on crop distributions and ozone concentrations to assess the benefits to agriculture of measures to reduce ozone

concentrations. In the United States, it was estimated that a national decrease in ozone concentrations of 40% would provide a net annual economic benefit of \$3000 million, or 2.8% of the national production. A similar recent exercise in Europe estimated that reducing current ozone exposures would have direct economic benefits to agriculture of about €2000 million annually. Such national or international estimates disguise the much greater losses in particular crops and regions. For example, yield losses due to ozone levels in the 1980s in California were estimated to be in the range 20–25% for sensitive crops such as cotton, bean, and onions, an order of magnitude higher than the overall national estimate.

Such estimates have many uncertainties, including how well the exposure-response functions represent the real responses in different regions. They ignore the possible indirect effects of ozone through altered pest and pathogen damage; ozone has been shown to have both positive and negative effects on the prevalence of pests and diseases. Several major systemic pesticides reduce the impacts of ozone, and this may be a significant factor in the field. The estimates also ignore effects on crop quality; for example, ozone has been shown to reduce the oil content of oilseed rapeseeds, in addition to seed yield, producing a significant additional economic loss for the producer. In summary, these estimates can provide only an approximate guide to the possible regional economic significance of ozone.

In recent years, it has been possible to link global models of ozone production with exposure-response relationships to estimate effects on global food production. The results of one such exercise are shown in [Figure 5](#). This estimated that global yields of four staple crops (wheat, rice, maize, and soybean) were reduced by between 2 and 16% by modeled ozone concentrations in the year 2000. This is broadly consistent with a recent meta-analysis of experimental data for potato, barley, rice, wheat, bean, and soybean, which estimated that, at the current global ambient ozone concentrations of 30–50 ppb, mean yield losses for the different crops range from 5 to 19%.

Importantly, there are significant regional variations in the estimated yield losses, with those in densely populated parts of South and East Asia, for example, being substantially greater than the global average. There is an increasing body of experimental evidence to quantify effects on crop yields in these regions, and recent analysis of these experimental data has

Figure 4 Typical symptoms of visible leaf injury caused by elevated ozone concentrations in the field in Europe, showing leaves of (a) clover and (b) soybean. Image taken from <http://icpvegetation.ceh.ac.uk>.

Figure 5 Modeled global distribution of wheat yield loss for the year 2000. Reproduced with permission from van Dingenen, R., Dentener, F.J., Raes, F., Krol, M.C., Emberson, L., Cofala, J., 2009. The global impact on crop yields under current and future air quality legislation. *Atmospheric Environment* 43, 604–618.

suggested that the effects of ozone on yields of wheat and rice are greater than would be predicted based on exposure–response relationships derived from European and North American data. This evidence highlights ozone as a significant threat to crop yields in these regions.

Effects on Ecosystem Services

Managed and unmanaged ecosystems provide a wide range of services for human society. Over the past decade, ecologists have developed methods to categorize these services, and have begun to quantify and value the impacts of anthropogenic stresses, such as air pollution, on them. These ecosystem services can be divided into:

1. Provisioning services, e.g., the food, fuel, and fiber provided by ecosystems.
2. Regulating services, e.g., the ways in which ecosystems contribute to regulation of climate, water flow and quality, and pollination.
3. Cultural services, e.g., aesthetic and educational qualities of ecosystems, and their contribution to tourism and recreation.

The major effects of surface ozone on ecosystem services are described below. This summary does not include every type of ecosystem service, but focuses on those for which there is clear evidence of the adverse effects of ozone.

In terms of provisioning services, the effects of ozone on arable food production were described in the previous section, but effects on forests are also important. Numerous experimental studies in chambers have demonstrated the adverse effects of ozone on the growth of seedlings or saplings over periods of 1–5 years. Meta-analyses allow the identification of consistent effects of ozone in these studies, including reduced wood yield, shorter height, and smaller trunk diameter. Although some studies have shown effects of both drought and elevated CO_2 in reducing the impacts of ozone, these effects are not consistently found in the meta-analysis. Overall, the

evidence from this analysis suggests that current global ozone concentrations reduce tree biomass by about 7%.

However, there are major questions over how the results from these short-term experiments of 1–5 years' duration can be extrapolated over a tree's lifetime. Contrasting results from two long-term open-air fumigation experiments illustrate the uncertainties in these extrapolations. In the AspenFACE study, results after the first few years showed a clear effect of ozone in reducing the growth of aspen trunks, but after 12 years there was no effect of ozone on aspen trunk growth. The reason for this is that the original planting included aspen clones differing in sensitivity to ozone, and the tolerant clones had a selective advantage over the sensitive clones in elevated ozone. Hence after 12 years, the effect of ozone was dominated by that of the tolerant clones, and was lower than that in the early years of the experiment. In contrast, doubling the ambient ozone concentrations in the Kranzberg free-air release system led to almost a 50% reduction in trunk growth in beech, but not in spruce, a greater effect than initial observations of changes in stem diameter suggested. The difference between the outcomes in these two unique experiments has enormous implications for long-term modeling of ozone effects on forest production.

Furthermore, even these long-term experiments cannot capture the complexity of ozone effects on forest ecosystems over periods of decades. The area where the long-term impacts of ozone stress on forest community composition have been most intensively studied is in the mountains around Los Angeles, where effects began to be observed in the 1960s. The dominant species of these mixed-conifer forests prior to European settlement (ponderosa pine and Jeffrey pine) are also the most sensitive species to ozone. Both species have shown severe ozone injury and reduced needle lifetimes, which are associated with reduced radial growth, or years with missing growth rings. Trees affected by ozone are more susceptible to attack by bark beetles, which are often the direct cause of mortality; outbreaks of bark beetles are associated with drought years. Regeneration in these forests is now greater for species such as white fir, which are more resistant to ozone, a similar mechanism to that which led to the domination of tolerant

aspen clones in the AspenFACE experiment. Current fire-exclusion policies favor replacement of ponderosa pine and Jeffrey pine by more fire-sensitive species that also happen to be more ozone tolerant. This example illustrates the complex interactions with management practices, pest outbreaks, and climate that may influence the long-term impacts of ozone on forests.

Effects of ozone on the provisioning services provided by pastures are also economically important. Most studies suggest that total harvested production is only affected at very high ozone exposures, but that shifts in species composition, and in particular a reduction in the proportion of legume species in the harvested material, can occur at lower exposures. This has been shown to reduce the nutritional quality of the crop for grazing animals, although no study has yet shown directly a link between ozone exposure and meat or milk production.

The changes in forest production as a provisioning service also have implications for the regulating ecosystem services, and in particular climate regulation. Terrestrial ecosystems, and forests in particular, are an important component of the global carbon cycle, and reductions in the amount of carbon sequestered in ecosystems will lead to increases in atmospheric CO₂ concentrations, and hence more rapid warming of the planet. The reductions in wood production described above will reduce carbon sequestration and climate regulation, but three other effects of ozone also need to be considered:

- Effects of ozone on the sequestration of carbon below-ground are important, as well as effects on sequestration above-ground. For example, in the AspenFACE experiment, elevated ozone halved the formation of the stable fraction of soil carbon, which is not readily exchanged with the atmosphere, while the Kranzberg experiment showed that ozone reduced the CO₂ sink strength both above-ground and below-ground.
- Ozone may modify the flux of CO₂ from soils to the atmosphere through respiration. In both the AspenFACE and Kranzberg experiments, an increased rate of soil respiration was reported, but other experiments have reported no effects, or negative effects, of ozone on soil respiration.
- Ozone exposure can modify fluxes to the atmosphere of other radiatively active gases. For example, ozone alters fluxes of nitrous oxide and methane from rice paddies and peatlands, although the size and direction of these effects remain uncertain.

Overall, there is a large potential effect of ozone on climate regulation, but inconsistencies in the results from different studies, and the lack of integrated estimates of effects on the whole ecosystem carbon budget, mean that the size of these effects cannot be confidently predicted.

Ozone can reduce transpiration rates from a plant community, both because of reduced leaf area per unit ground area, and because it often causes a closure of the stomata. However, recent evidence has demonstrated that ozone exposure also interferes with the hormonal signals that control the normal closure of stomata in response to soil drying. Hence ozone exposure causes a loss of stomatal control of water loss by the plant, and can exacerbate the adverse effects of drought conditions. Although few studies have upscaled these findings to a whole stream catchment,

there is evidence that ozone can modify the ecosystem regulation of water flows provided by forests.

Pest and disease regulation is an important ecosystem service that may be modified by ozone, but the direction of these effects is very uncertain, with evidence that direct effects on the pest or disease organisms, modification of leaf surface properties, changes in food quality, increased predation, and changes in production of defense compounds are all important. Within a single experiment, a range of effects on pests and diseases may be reported. For example, effects of ozone within the AspenFACE study include increased aphid numbers, increased growth of tent caterpillars, and increased rust infection of leaves.

Ozone can affect both the regulating and cultural services provided by many natural, or seminatural, plant communities. For example, in plant communities such as traditional hay meadows or woodlands, seasonal flowering is an important cultural service attracting tourists and providing aesthetic value, as well as being linked to the regulating service of pollination. Ozone can both reduce and delay flowering, leading to detrimental effects on these ecosystem services.

Many native plant species, when grown alone, are as sensitive to short-term experimental ozone exposures as the most sensitive crop species. The range in sensitivity between and within these plant species means that competition between and within species may be modified by ozone, leading to changes in species composition and, potentially, the loss of sensitive species or genotypes, with a loss of genetic resources, another important ecosystem service. The available evidence from short-term chamber experiments with simple sown species mixtures, or transplanted cores taken from the field, clearly demonstrates that more sensitive species are at a competitive disadvantage under elevated ozone. However, as for forests, such experiments are of limited value in assessing the long-term impact of ozone on biodiversity in the complex plant communities found in the field.

Two recent long-term open-air fumigation experiments on upland grassland communities in Switzerland and the UK show contrasting effects of ozone. In the former, there were few significant effects of ozone on species composition of a species-rich grassland, suggesting that such systems are relatively tolerant to ozone. In contrast, the latter showed significant shifts in species composition in an upland hay meadow undergoing a change in management. One potential reason for the greater response in this system is the fact that a hay rattle, a keystone species in these communities (i.e., one that modifies the response of other species, in this case, through selective parasitism), appears to be very sensitive to ozone. Hence the precise effects of ozone on the ecosystem services provided by such seminatural plant communities may be hard to predict and depend on unique characteristics of individual communities.

Ozone as a Component of Future Global Environmental Change

There is evidence from Europe and North America that peak concentrations of ozone during photochemical episodes have declined over the last two decades, reflecting the effect of regional strategies to control precursor emissions. However, there is also evidence that, over the same period, annual mean

concentrations have increased. This is believed to reflect an increase in northern hemispheric background tropospheric concentrations as a result of increased precursor emissions at a hemispheric scale. Decreased peak ozone concentrations would be expected to reduce the extent of visible injury and the size of any reductions in plant growth. However, increased background concentrations over the range 30–50 ppb will increase effects on vegetation. Model projections over this century suggest that, while ozone concentrations over much of the developed world will have decreased by 2050, those in developing countries will continue to increase, as will northern hemispheric background concentrations. However, very few experiments have been designed to assess the effect of these changing exposure patterns.

Furthermore, any analysis of the implications of these future changes in surface ozone for global food production, and for global ecosystem services, needs to be conducted, not in isolation, but in the context of a wider assessment of global environmental change, for four major reasons:

1. Elevated CO₂ concentrations reduce the effect of ozone on plant growth and crop yield. This is because they decrease stomatal conductance, reducing the flux of ozone to sites of damage in the leaf, and they also increase the leaf antioxidant defense capacity. However, there are exceptions. For example in the AspenFACE study referred to earlier, elevated CO₂ concentrations prevented any adverse effects of increased ozone exposure on tree growth and many other variables. However, the effects of ozone of leaf senescence, bud burst, insect and fungal damage, and regulation of water loss were not prevented by exposure to elevated CO₂.
2. Ozone effects may be modified by climate, while ozone exposure may exacerbate the impact of climatic stress on vegetation. While drier and warmer conditions might reduce the flux and short-term impacts of ozone episodes, decreased root growth under ozone stress might increase the impact of droughts. These climatic interactions may also be indirect. For example, warmer winters may be associated with earlier bud burst or crop emergence, leading to greater exposure to elevated hemispheric background ozone concentrations at a sensitive early stage of plant development.
3. Ozone exposure can modify the global carbon cycle, with important indirect effects on global warming, since it reduces photosynthesis, growth, and carbon sequestration. Models that have scaled up from experimental studies on young trees suggest that the adverse effects of global ozone concentrations on forest production could significantly reduce the size of the terrestrial carbon sink. One model estimate suggests that the indirect effect of ozone on radiative forcing, caused by reducing the land carbon sink by 143 PgC over this century, may be as large as the direct radiative forcing due to ozone. However, these models have tended to only consider effects on above-ground growth, and need to be extended to include effects of ozone on the full carbon cycle, including carbon sequestered in the soil and the fluxes of CO₂ and other radiatively active gases from the soil.
4. Ozone may act in combination with climate and environmental change, and changes in population and food

consumption, to threaten global food security. Global models suggest that the proportion of the world's crops exposed to ozone levels above threshold exposures for significant effects on yield will increase significantly over the next two decades. Much of this increased area of agricultural production at risk is likely to be in the rapidly developing regions of Asia, Latin America, and Africa. The economic and social implications of widespread loss of yield of staple crops could be very serious in countries with rapidly increasing populations and loss of productive land. Unfortunately, there is little direct evidence of the significance of ozone impacts on agriculture in these areas. There is an urgent need to extend current risk assessment methods for ozone to these regions of the planet, in order to link this issue more effectively with wider policy evaluation.

In conclusion, surface ozone effects on vegetation are likely to increase in severity at a global scale over the first half of this century, although there will be major regional variations. Ozone needs to be considered as an important component of global environmental change that will have major impacts on the planet's vegetation cover, alongside the changing effects of CO₂ concentrations, climate, and other environmental stresses.

Surface Ozone (Human Health)

M Lippmann, New York University, Tuxedo, NY, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Ozone (O_3) is formed in ambient air at the earth's surface by photochemical reactions during daylight hours, and is inhaled by people engaged in normal outdoor activities, with much greater dosages during strenuous physical activity and their associated increases in lung ventilation. The dosage indoors is much lower due to O_3 's poor penetration into indoor spaces, its rapid reaction with indoor surfaces, and minimal lung ventilation during sedentary activities. The inhaled O_3 reacts with lung epithelia from the trachea to the respiratory acinus, and (1) causes transient reductions in pulmonary capacity and (2) increases in pulmonary inflammation and permeability. These effects are highly variable from person-to-person, and are considered to be adverse effects in sensitive subjects. There are also cumulative effects from chronic exposures in humans and laboratory animals, but these effects have not been as well characterized as the acute effects.

Introduction

Ozone (O_3) is almost entirely a secondary air pollutant, formed in the atmosphere through a complex photochemical reaction sequence requiring reactive hydrocarbons (HCs), nitrogen dioxide (NO_2), and sunlight. O_3 can only be controlled by reducing ambient air concentrations of HC, NO_2 , or both. Motor vehicles are one of the major categories of sources of HC, NO_2 , and nitric oxide (NO). NO and NO_2 combined, referred to as NO_x , along with HC, have been the target of control efforts and major reductions (>90%) have been achieved in HC emissions per vehicle. Substantial reductions in NO_x emissions from motor vehicles and power plants are now being implemented.

We know a great deal about O_3 chemistry and have developed highly sophisticated O_3 air quality models. Unfortunately, the models, and their applications in control strategies, have clearly been inadequate in terms of meeting national and local air quality goals. We also know a great deal about some of the health effects of O_3 . However, much of what we know relates to transient, apparently reversible effects that follow acute exposures lasting from 5 min to 8 h. These effects include changes in lung capacity, flow resistance, epithelial permeability, and reactivity to bronchoactive challenges; such effects can be observed within the first few hours after the start of the exposure and may persist for many hours or days after the exposure ceases. Repetitive daily exposures over several days or weeks can exacerbate and prolong some of these transient effects, while ameliorating others.

Decrements in respiratory functions such as forced vital capacity (FVC), as measured by the air volume that can be expelled from fully inflated lungs with a maximal effort, and forced expiratory volume in the first second of a vital capacity maneuver (FEV_1) fall into the category where adversity begins at some specific level of pollutant-associated reduction. However, there are clear differences of opinion on what the threshold of adversity ought to be, especially for the more sensitive members of the population.

For O_3 , the only significant exposure route is inhalation, and exposure can be defined as the concentration at the nose and mouth. Local outdoor concentrations are reduced in the vicinity of heavy vehicular traffic, owing to scavenging of O_3 by

NO. On the other hand, less trafficked areas downwind may have higher O_3 concentrations because of the enrichment of the air mass with motor vehicle exhaust, precursor chemicals, and because of active photochemistry. Thus, outdoor O_3 concentrations can be either higher or lower than those measured at central monitoring sites. Indoor concentrations of O_3 are almost always substantially lower than those outdoors because of efficient scavenging by indoor surfaces and the lack of indoor sources.

Exposures are the only one determinant of O_3 dose, which are also determined by the volume of air inhaled and the pattern of uptake of O_3 molecules along the respiratory tract. When people work or exercise outdoors, and thereby increase their rate of ventilation, the contribution of outdoor exposure to total O_3 dose generally becomes the dominant factor. The dose to target tissues in the respiratory acini (the region from the terminal bronchioles through the alveolar ducts) increases even more with exercise than does total respiratory tract dose, since O_3 penetration to the acini increases with tidal volume and flow rate.

Types of Studies

Controlled Human Exposures

There is a very large database from studies in which selected human volunteers were exposed to O_3 in purified laboratory air for specific times. In most studies, a series of exposures took place in random order, and included exposures at one or more concentrations, as well as a sham exposure to purified air. Many involved prescribed periods and intensities of exercise during the exposure interval. The most commonly measured effects were changes in forced expiratory flow rates and volumes and/or changes in airway resistance and compliance.

The advantages of controlled human exposure studies are (1) the opportunity to carefully select and carefully characterize the subjects, whether they be healthy normals, asthmatics, smokers, etc.; (2) the willingness and ability of most volunteer subjects to perform various levels and durations of exercise during the exposures; (3) the ability to deliver and monitor the preselected challenge atmospheres during the exposure; (4) the ability of the subjects to reproducibly perform respiratory

maneuvers required for some functional assays and to provide information on symptomatic responses; and (5) avoidance of the need to make interspecies extrapolations.

The major limitations of controlled human exposures are that (1) ethical constraints limit the challenges and effects of assays that can be performed (i.e., challenges that produce only transient functional changes); (2) the numbers of repetitive challenges and assays are limited by subject tolerance and cooperation; and (3) the number of subjects that can be studied is limited by the generally large costs of performing the studies and/or by the availability of sufficient numbers of subjects with the desired characteristics.

Natural Human Exposures

There is also a human database from studies of the responses of natural populations to exposures to ambient air pollutants. Among the more difficult challenges of such studies some are (1) identifying an accessible population at risk whose relevant exposures can be defined and adequately characterized; (2) collecting an adequate amount of suitable quality-assured data on exposure and responses; and (3) collecting sufficient data on identifiable characteristics of the individuals and of their environmental exposures to other agents that may influence the response variables and thereby confound any of the hypothesized pollutant exposure–response relationships that may be present.

The basic design premise in field studies is to maximize the signal-to-noise ratio for the pollutant exposure–response relationships. The noise on the response side of the relationships has been the focus of much work, and guidance on these aspects is available from the American Thoracic Society. There has been less focus on the reduction of the noise in the exposure variables. An opportunity was created by the recognition that the summer haze is regional in scale and is enriched in secondary air pollutants such as O_3 and sulfuric acid (H_2SO_4), both of which form gradually during daylight hours in air masses containing diluted primary pollutants transported over long distances from industrial, power plant, and motor vehicle sources, especially SO_2 , NO_2 , and HC. Therefore, studies of populations were undertaken in communities remote from local sources of air pollution, primarily in wooded regions where ammonia (NH_3) sources, which would rapidly neutralize the H_2SO_4 , would also be minimal.

In studies of acute responses to the inhalation of secondary air pollutants, it is not possible to identify a nonexposed (control) population. On the other hand, the concentrations of the secondary pollutants have large temporal variations. There are both diurnal variations, with peak concentrations generally occurring in the afternoon, and day-to-day variations in concentration associated with the trajectory of the air mass over pollutant-precursor source areas, atmospheric stability, intensity of incident solar radiation, temperature, and humidity. Thus, the volunteer subjects are exposed to different concentration profiles each day.

Population-Based Studies of Chronic Health Effects

Neither controlled human exposure studies in the laboratory nor natural human exposure studies in the field can provide any direct information on chronic effects of prolonged human

exposures to O_3 . The only way to get such information is to compare group-average measures of function, symptom frequency, lost activity days, hospital admissions, clinic visits, medical diagnoses, etc. with estimates of area-wide chronic exposure intensity.

Because of the large number of possible confounding factors and the difficulty of properly classifying exposures, very large populations must be studied in order to find significant associations between group-average exposures and effects. Any statistically significant effects that are attributed to O_3 would tend to be underestimated because of the influence of the confounding factors.

Alternatively, they could be spurious if the effects are really caused by variables that are colinear with O_3 .

Controlled Exposures of Laboratory Animals

The most convenient and efficient way to study mechanisms and patterns of response to inhaled O_3 , and of the influence of other pollutants and stresses on these responses is by controlled exposures of laboratory animals. The transient functional responses to acute exposures can be measured and the differences in response among different animal species and between them and humans similarly exposed can be determined. Responses that require highly invasive procedures or serial sacrifice can also be obtained to gain information that cannot be obtained from studies on human volunteers. Finally, long-term exposures in animals can produce cumulative responses that determine the pathogenesis of chronic disease. Other advantages of studies on animals are the ability to examine the presence of, and basis for, variations in response that are related to age, sex, species, strain, genetic markers, nutrition, the presence of other pollutants, and so on. As in controlled human exposure studies, the concentrations and durations of the exposure can be tightly controlled, as can the presence or absence of other pollutants and environmental variables. Another important advantage of controlled animal studies is that relatively large numbers of individuals can be exposed simultaneously, creating the possibility of detecting responses that affect only a limited fraction of the population.

Among the significant limitations to the use of exposure-response data from animal studies, human risk assessments are quite limited ability to interpret the animal responses in relation to likely responses in humans who might be exposed to the same or lower levels. Controlled chronic exposure protocols can be very labor intensive and expensive, which tend to limit the number of variables that can effectively be examined in any given study.

Effects of Single Exposures to Ozone

Respiratory Mechanical Function Responses

There are more data on respiratory function responses than on any of the other coincident responses to short-term O_3 inhalation. It is well established that the inhalation of O_3 causes concentration-dependent mean decrements in exhaled volumes and flow rates during forced expiratory maneuvers, and that the mean decrements increase with increasing depth of

breathing and the duration of the exposure. There is a wide range of reproducible responsiveness among healthy subjects and functional responsiveness to O_3 is no greater, and usually lower, among cigarette smokers, older adults, and patients with chronic obstructive pulmonary disease.

Healthy children at summer camps with active outdoor recreation programs had greater decrements in lung function than children exposed to O_3 at comparable concentrations in chambers for 1 or 2 h. Furthermore, their activity levels were considerably lower than those of the children exposed in the chamber studies while performing very vigorous exercise. Since it is well established that functional responses to O_3 increase with levels of physical activity and ventilation, the greater responses in the camp children had to be caused by other factors, such as greater cumulative exposure, or by the potentiation of the response to O_3 by other pollutants in the ambient air.

A study of children with moderate to severe asthma was performed at a summer camp in New England, and the decrements in peak expiratory flow rates associated with ambient O_3 concentrations were similar in magnitude to those reported for healthy children at other summer camps in the Northeastern United States. However, the level of physical activity of the asthmatic children, and hence their O_3 intake, was much lower. Also, the asthmatic children had less reserve functional capacity. Thus, the level of health concern for such comparable functional decrements is much greater.

Field studies have also been done of functional responses of adults engaged in relatively brief (0.5 h) recreational activities outdoors in the presence of varying levels of O_3 . The magnitudes of the functional decrements per unit of ambient O_3 concentration were similar to those observed in volunteers exposed while exercising vigorously for 1 or 2 h in controlled chamber exposure studies.

The observations from the field studies in the children's camps stimulated the Environmental Protection Agency (EPA) Clinical Studies Laboratory in Chapel Hill, NC, USA, to undertake a chamber exposure study of adult male volunteers involving 6.6 h of O_3 exposure. Moderate exercise was performed for 50 min per hour for 3 h in the morning and again in the afternoon. The functional decrements become progressively greater after each hour of exposure. The effects were transient in that there were no residual functional decrements on the following day. The decrements in FEV_1 after 6.6 h of exposure to O_3 concentrations of 120 parts per billion (ppb) averaged 13.6% and were comparable to those seen previously in the same laboratory on similar subjects following 2 h of intermittent heavier exercise at 220 ppb. Follow-up studies were done on adult males with 6.6 h exposures at 80 and 100 ppb, as well as at 120 ppb. Those at 80 and 100 ppb showed lesser changes that also became progressively greater after each hour of exposure.

Evidence of the time scale for the biological integration of O_3 exposure can also be deduced from the rate at which the effects dissipate. In one study, young adult females were exposed in a protocol that produced a mean decrement in FEV_1 of 21%. After 18 h, their mean decrement was down to 4%, and at 42 h it was 2%.

The time scale for the biological integration of the effects of a single O_3 exposure has also been examined in studies on laboratory animals. Rats can provide a good test model for the observed human responses to O_3 , even though they are a less

sensitive species than humans. The lesser responses are consistent with the lesser retention of inhaled O_3 by rats.

The large interindividual variability of O_3 -induced functional responses is not yet understood, and functional responses in individuals do not correlate well with other responses. Based on the large database accumulated over a 10-year period at the EPA Clinical Studies Laboratory, O_3 concentration explained 31% of the variance in FEV_1 responses, and subject age explained only another 4%. For individuals exposed two or more times for 6.6 h, 47% of those exposed to 120 ppb had an FEV_1 decrement of 10% or greater. Respiratory function effects can accumulate over many hours, and an appropriate averaging time for transient functional decrements caused by O_3 is 6 h. This was a major factor for the change in the averaging time for the primary O_3 standard in the United States from 1 to 8 h. Another factor was the recognition that O_3 exposures in ambient air can have broad peaks with 8-h averages equal to 90% of the peak 1-h averages. While there is a great deal of knowledge about O_3 exposure-respiratory function response in humans, as summarized above, we still know very little about the mechanisms responsible for the responses.

Effects on Aerosol Dispersion

As discussed above, acute exposures of humans to low levels of O_3 cause decreases in lung function. However, there is also a potential for small airways responses that do not produce measurable changes in conventional respiratory function indices. In tests of aerosol dispersion, an aerosol bolus is injected into the tidal breath at three different depths, and the primary measure of bolus dispersion is the expired bolus half-width (HW). The HW increased significantly following O_3 exposure relative to air exposure accounted for less than 25% of the variance. Changes in aerosol dispersion seen with O_3 exposure were related to changes in turbulent mixing and/or regional time constants in the small airways, suggesting a possible O_3 effect in that region of the lung as well as effects in the larger airways that produce the respiratory function decrements.

Symptomatic Responses

Respiratory symptoms have been closely associated with group mean pulmonary function changes in adults acutely exposed in controlled exposures to O_3 and in ambient air containing O_3 as the predominant pollutant. In controlled 2-h O_3 exposures, some heavily exercising adult subjects experienced cough, shortness of breath, and pain on deep inspiration at 120 ppb O_3 , although the group mean response was statistically significant only for cough. Above 120 ppb O_3 , respiratory and nonrespiratory symptoms have included throat dryness, chest tightness, substernal pain, cough, wheeze, pain on deep inspiration, shortness of breath, dyspnea, lassitude, malaise, headache, and nausea. The prolonged exposure studies involving 6.6 h of exposure at concentrations between 80 and 120 ppb also produced significant increases in respiratory symptoms including cough and pain on deep inspiration. Although O_3 causes symptomatic responses in adults at current peak levels, there is a large set of data indicating that such responses do not occur in healthy children.

These laboratory results are consistent with the results obtained in field studies of healthy children at summer camps, which failed to find any symptomatic responses despite the occurrence of relatively large decrements in function that were proportional to the ambient O₃ concentrations.

Epidemiological studies have provided evidence of qualitative associations between ambient oxidant levels <100 ppb and symptoms in children and young adults, such as throat irritation, chest discomfort, cough, and headache. Symptoms reported in individuals exposed to O₃ in purified air are similar to those found for ambient air exposures except for eye irritation, a common symptom associated with exposure to the ambient mixtures of photochemical oxidants, which has not been reported for controlled exposures to O₃ alone.

Morbidity

Associations between ambient air pollutants and respiratory morbidity were examined using the Health Interview Survey, a large cross-sectional database collected in the United States by the National Center for Health Statistics. The results indicate an association between fine particulate pollutants and both minor restrictions in activity and respiratory conditions severe enough to result in work loss and bed disability in adults. Ozone, on the other hand, was associated only with the more minor restrictions.

Studies examining associations between the daily average concentrations of ambient air pollutants and daily hospital admissions for respiratory disease have found consistent associations in summer between hospital admissions for respiratory disease and daily levels of sulfate, O₃, and temperature, but no comparable associations for a group of non-respiratory conditions. The effect of ambient O₃ on hospital admissions for respiratory causes ranges from one to three total respiratory admissions per day per 100 ppb O₃ per 10⁶ persons, or from a relative risk per 100 ppb O₃ of 1.1–1.36.

Another index of respiratory morbidity in asthmatics is physician-authorized use of medication. In the previously cited study of children with moderate to severe asthma, the camp physician authorized supplemental asthma medication to children in the group at a rate proportional to the ambient O₃ concentration.

Effects on Athletic Performance

It has been more than four decades since epidemiological evidence from Southern California suggested that the percentage of high school track team members failing to improve performance increased with increasing oxidant concentrations in the hour before a race. The effects may have been related to increased airway resistance or to associated discomfort, which may have limited motivation to run at maximal levels. Subsequent controlled exposure studies of heavily exercising competitive runners have demonstrated decreased function at 200–300 ppb.

There are animal models for decreased performance during O₃ exposure. Rats and mice were exposed for 6 h to O₃ at 80, 120, 250, or 500 ppb while housed in running wheels. Running in both species decreased in a concentration-related manner during exposure to O₃, with the decrease being greater with

increasing time of exposure. The decrease in running activity produced by O₃ persisted for several hours after exposure.

Effects on Airway Reactivity

Exposure to O₃ can also alter the responsiveness of the airways to other bronchoconstrictive challenges as measured by changes in respiratory mechanics. Tests involving exposures of healthy subjects to 80, 100, and 120 ppb for 6.6 h produced, respectively, 56, 89, and 121% increases in methacholine responsiveness. Increased responsiveness to methacholine was also seen with 1 h at 350 ppb in young adult males with allergic rhinitis after exposure to O₃. In subjects with asthma, changes in FEV₁, methacholine responsiveness, and allergen responsiveness did not correlate with each other. The O₃-induced responsiveness does not appear to be dependent on the presence of inflammatory cells in the small airway wall.

Effects on Airway Permeability

The effects of inhaled O₃ on respiratory epithelial permeability were studied in healthy, nonsmoking young men exposed for 2 h to purified air and 400 ppb O₃ while performing intermittent treadmill exercise at 67 l min⁻¹. Seventy-five minutes after the exposures, the pulmonary clearance of a radioisotope-labeled organic molecule [^{99m}Tc]DTPA, was measured as an index of epithelial permeability. O₃ exposure sufficient to produce decrements in the respiratory function of human subjects also caused an increase in permeability. An increased permeability could facilitate the uptake of other inhaled toxicants and/or the release of inflammatory cells such as neutrophils onto the airway surfaces.

Effects on Airway Inflammation

O₃-induced airway reactivity to methacholine is also associated with neutrophil influx into the airways and with changes in cyclooxygenase metabolites of arachidonic acid. Inflammatory and biochemical changes in the airways also occur following O₃ exposure. The inflammatory process caused by O₃ exposure is promptly initiated and persists for at least 18 h. Cells and enzymes capable of causing damage to pulmonary tissues were increased, and the proteins that play a role in the fibrotic and fibrinolytic processes were elevated as a result of O₃ exposure.

The weight of the evidence from these results, showing both functional and biochemical responses in humans and laboratory animals that accumulate over multiple hours and persist for many hours or days after exposure ceases, is clear and compelling. Both functional changes and inflammatory processes were shown to occur in humans following exposures to 100 ppb O₃ for 6.6 h, whereas higher concentrations were required to elicit comparable responses in rats. Thus, the rat data, which provide evidence of other effects as well, appear to provide conservative indications of effects in humans.

Effect of Single and Multiday Exposures on Particle Clearance from the Lungs

The effect of 2-h exposures to 200 or 400 ppb O₃ with intermittent light exercise on the rates of tracheobronchial

mucociliary particle clearance was studied in healthy adult males. The 200 ppb O₃ exposure produced a significant acceleration of particle clearance in peripheral airways but failed to produce a significant reduction in FVC, suggesting that significant changes in the ability of the deep lung to clear deposited particles take place before significant changes in respiratory function take place.

Effects of Single and Multiday Exposures on Lung Infectivity

Both *in vivo* and *in vitro* studies in animals have demonstrated that O₃ can affect the ability of the immune system to defend against infection. Increased susceptibility to bacterial infection has been reported in mice at 80–100 ppb O₃ for a single 3-h exposure. Related alterations of the pulmonary defenses caused by short-term exposures to O₃ include impaired ability to inactivate bacteria in rabbits and mice and impaired macrophage phagocytic activity, mobility, fragility and membrane alterations, and reduced lysosomal enzymatic activity. Some of these effects have been shown to occur in a variety of species including mice, rats, rabbits, guinea pigs, dogs, sheep, and monkeys.

Effects of Multiday and Ambient Episode Exposures

Since single exposures lasting for an hour or more at current peak ambient O₃ levels produce measurable biological responses in healthy humans, and since there is a high probability that one high-O₃ day will be followed by several more high-O₃ days, it is important to know the extent to which the effects accumulate or progress over multiple days. The data on functional adaptation are largely, but not exclusively, based on studies in human volunteers, whereas the database on biochemical and structural changes caused by O₃ is based entirely on studies in laboratory animals.

It is well established that repetitive daily exposures, at a level that produces a functional response upon single exposure, result in an enhanced response on the second day, with diminishing responses on third and fourth day and virtually no response by fifth day.

For repeated 6.6 h per day exposures to 120 ppb O₃, the peak functional response occurs on the first day, with progressively lesser responses after the second, third, and fourth days of exposure. However, for these same subjects, their responsiveness to methacholine challenge peaked on the second day, and remained elevated throughout all 5 days of exposure. The persistent elevation of airway responsiveness is one reason to discount the view held by some that the functional adaptation phenomenon indicates that transient functional decrements are not an important health effect. Additional evidence comes from research in animals showing that persistent damage to lung cells accumulates even as functional adaptation takes place.

Chronic Effects of Ambient Ozone Exposures

The chronic effects database includes a quite limited amount of information on human effects and a more substantial volume

of data on effects seen in laboratory animals undergoing chronic exposures.

Controlled Laboratory Exposure Studies: Human Responses

A study in Southern California provided evidence for a seasonal adaptation of lung function. In this study, a group of subjects selected for their relatively high functional responsiveness to O₃ had much greater functional decrements following 2 h of exposure to O₃ at 180 ppb with intermittent exercise in a chamber in the spring than they did in the following fall or winter, although their responses in the following spring were equivalent to those in the preceding spring. These findings suggest that some of the variability in acute response coefficients reported for earlier controlled human exposures to O₃ in chambers could have been related to seasonal variations in responsiveness, which, in turn, may be related to a long-term adaptation to chronic O₃ exposure.

Epidemiological Studies

Reports of populations of children living in Southern California indicate that chronic air pollutant exposures can affect lung development as measured by growth in respiratory function. However, O₃ was not among the pollutants that correlated with lung development. Rather, the effect was associated with particulate matter, NO₂, and acidic vapors.

There was some limited evidence for chronic effects of O₃ based upon an analysis of pulmonary function data in a national population study in 1976–80 – the second National Health and Nutrition Examination Survey. Using ambient O₃ data from nearby monitoring sites, a highly significant O₃-associated reduction in lung function was seen for people living in areas where the annual average O₃ concentrations exceeded 40 ppb.

A prospective study of a cohort of Seventh Day Adventists living in California reported an O₃-associated increase in the number of men developing adult-onset asthma, but not of women. It was suggested that the effect in men might have been due to their greater time spent out of doors and engaged in strenuous activities that could have resulted in more O₃ inhalation.

The limited evidence available to date for the effect of O₃ on longevity is also largely negative. A study utilizing the Public Use Sample containing data on 2 million individuals in the United States obtained both death certificate data and air pollution network data in eight regions of the United States. Highly significant and consistent associations with mortality were found for SO₄²⁻. Significant, but weaker and less consistent associations were seen for SO₂ and CO. No significant associations were seen for O₃ or NO₂.

Controlled Laboratory Exposure Studies: Animal Responses

The highest O₃ dose is received at the acinus, where the terminal bronchioles lead into alveolar ducts, and a series of studies have shown that the effects of inhaled O₃ on lung structure are also greatest in this region. Morphometric techniques selectively focused on this limited region of the lung showed that significant changes occurred in the alveoli

just distal to the terminal bronchioles in rats exposed for 12 h per day for 6 or 12 weeks to 120 or 240 ppb O₃. In both juvenile and adult rats, there were significant increases in the numbers of alveolar type I and type II epithelial cells and alterations in the interstitium and endothelium. From physiological studies of rats that were simultaneously exposed, there were significant increases in the vital capacity and end-expiratory volume that suggested alterations in distensibility of the lung tissue.

Studies at relatively low O₃ concentrations have also been done in monkeys exposed to O₃ for 8 h per day for 6 or 90 days to 150 or 300 ppb O₃. Responses included ciliated cell necrosis, shortened cilia, and secretory cell hyperplasia with less stored glycoconjugates in the nasal region. Respiratory bronchiolitis observed at 6 days persisted to 90 days of exposure. Even at the lower concentration of 150 ppb O₃, nonciliated bronchiolar cells appeared hypertrophied and increased in abundance in respiratory bronchioles.

For some chronic effects, intermittent exposures can produce greater effects than those produced by a continuous exposure regime that results in higher cumulative exposures. Two groups of 7-month-old male monkeys were exposed to 250 ppb for 8 h per day either daily or, in the seasonal model, daily in alternate months during a total exposure period of 18 months. A control group breathed only filtered air. Monkeys from the seasonal exposure model, but not those exposed daily, had significantly increased total lung collagen content, chest wall compliance, and inspiratory capacity. All monkeys exposed to O₃ had respiratory bronchiolitis with significant increases in related morphometric parameters. Lung growth was not completely normal in either exposed group. Thus, long-term effects of oxidant air pollutants that have a seasonal occurrence may be more dependent on the sequence of polluted and clean air than on the total number of days of pollution, and estimations of the risks of human exposure to seasonal air pollutants from effects observed in animals exposed daily may underestimate long-term pulmonary damage.

Summary and Conclusions

The apparently reversible effects that have followed acute exposures lasting from 5 min to 6.6 h include changes in lung capacity, flow resistance, epithelial permeability, and reactivity to bronchoactive challenges. These effects may persist for many hours or days after the exposure ceases. Repetitive daily exposures over several days or weeks can exacerbate and prolong these effects.

Most of the data available on transient functional effects of O₃ were obtained from controlled human exposure studies and field studies of limited duration. Such studies can provide information on chronic pollutant effects only to the extent that prior exposures affect the transient response to single-exposure challenges. Furthermore, interpretation of the results of such tests is limited by our generally inadequate ability to characterize the nature and/or magnitude of the prior chronic exposures. Most of the limited data we have on the effects of chronic O₃ exposures on humans come from epidemiological studies.

Epidemiological studies offer the prospect of establishing chronic health effects of long-term O₃ exposure in relevant populations and offer the possibility that the analyses can show the influence of other environmental factors on responses to O₃ exposure. On the other hand, the strengths of any of the associations may be difficult to establish firmly because of the complications introduced by uncontrolled cofactors that may confound or obscure the underlying causal factors.

In terms of functional effects, we know that single O₃ exposures to healthy nonsmoking young adults at concentrations in the range 80–200 ppb produce a complex array of pulmonary responses including decreases in respiratory function and athletic performance, and increases in symptoms, airway reactivity, neutrophil content in lung lavage, and rate of mucociliary particle clearance. Responses to O₃ in purified air in chambers occur at concentrations of 80 or 100 ppb when the exposures involve moderate exercise over 6 h or more and require concentrations of 180 or 200 ppb when the duration of exposure is 2 h or less. On the other hand, 45% mean FEV₁ decrements have been seen at 100 ppb of O₃ in ambient air for children at summer camps and for adults engaged in outdoor exercise for only 0.5 h. The apparently greater responses to O₃ in ambient air may be related to the presence of, or prior exposures to, acidic aerosols, but further investigation of this hypothesis is needed.

Exposure over successive days of adult humans in chambers to O₃ at current high ambient levels leads to a functional adaptation in that the responses are attenuated by the third day, and are negligible by the fifth day. On the other hand, a comparable functional adaptation in rats does not prevent the progressive damage to the lung epithelium. Daily exposures of animals also increase other responses in comparison to single exposures, such as a loss of cilia, a hypertrophic response of Clara cells, alterations in macrophage function, and alterations in the rates of particle clearance from the lungs.

The plausibility of accelerated aging of the human lung from chronic O₃ exposure is greatly enhanced by the results of a series of chronic animal exposure studies in rats and monkeys. There is little reason to expect humans to be less sensitive than rats or monkeys. On the contrary, humans have a greater dosage delivered to the respiratory acinus than do rats for the same exposures. Another factor is that the rat and monkey exposures were administered to confined animals with little opportunity for heavy exercise. Thus, humans who are active outdoors during the warmer months may have greater effective O₃ exposures than the test animals. Finally, humans are exposed to O₃ in ambient mixtures. The potentiation of the characteristic O₃ responses by other ambient air constituents seen in the short-term exposure studies in humans and animals may also contribute toward the accumulation of chronic lung damage from long-term exposures to ambient air containing O₃.

The lack of a more definitive database on the chronic effects of ambient O₃ exposures in humans is a serious failing that must be addressed with a long-term research program. The potential impacts of such exposures on public health deserve serious scrutiny and, if they turn out to be substantial, strong corrective action. Further controls on ambient O₃ exposure will be extraordinarily expensive and will need to be very well justified.

Introduction

Ice cores drilled in glaciers and ice sheets are used to investigate atmospheric chemistry, climate and glacier dynamics in the past. Precipitation that falls as snow in the polar regions, and at high altitudes in the tropical and temperate regions, if it survives summer warmth, is eventually transformed to glacier ice. Aerosols and soluble gases that are scavenged from the atmosphere by precipitation (wet deposition), or accumulate on the snow surface as dry deposition, are preserved within the ice. Atmospheric gases are also preserved in the form of air bubbles trapped within the ice. Ice cores are retrieved by means of a mechanical or thermal drill that cuts an annulus around a central, vertical core that is typically 10–20 cm in diameter and a few tens of meters to several thousand meters in length. If the relationship between length along the core and time in the past is known, time-series of atmospheric composition can be derived. The best-known example is the record of carbon dioxide from Antarctic ice cores, which documents significant changes in concentration of this important greenhouse gas over the last several hundred thousand years of Earth history. Time-series have also been developed from ice cores for many other trace gases and aerosol species, and, indirectly, of atmospheric temperature, atmospheric dynamics, solar variability, and marine and terrestrial biogeochemical cycles. Because most of this information is unavailable from any other source, ice cores play a central role in our understanding of paleoclimate. Data from ice cores also serve as a baseline of natural variability against which contemporary changes in the atmosphere may be evaluated.

Glacier Ice and Ice Core Dating

Ice core studies are conducted at perennially cold sites where little or no melting occurs. Examples include Antarctica, the interior portions of Greenland, the small ice caps of Arctic

Canada, and the high mountains of the Andes and the Himalaya. Under such conditions, there is net snow accumulation in most years, and a combination of mass loading and metamorphism leads to compaction of the snow and eventual transition to glacier ice. Buildup of ice masses reaches from hundreds of meters thick in alpine settings to several kilometers in the great polar ice sheets of Antarctica and Greenland. This buildup is balanced by the slow deformation of glacier ice under pressure. Flow by internal deformation and sliding along the bed brings ice into warmer, lower-elevation environments where it is lost to melting, sublimation, or iceberg calving. Because of compaction and flow, snow layers of original thickness λ at the surface become thinner with depth. The amount of time t for a layer to reach depth z cannot generally be determined directly, but can be estimated with a geophysical ice flow model, used to calculate a thinning function $\psi = \lambda(z, 0)/\lambda(0, -t)$, if the net snow accumulation rate $\dot{b}(-t)$ is known. Ice core drilling sites are usually chosen near an ice divide (analogous to a drainage divide in hydrology), where the dominant strain direction is vertical. This greatly simplifies the calculation of ψ , which in this case will be approximately exponential. Under favorable circumstances, age and layer thickness can be determined by direct visual observation, using the alternating layering of coarse-grained, dusty, and wind-packed summer snow and relatively uniform winter snow. Counting of visible annual layers and seasonal cycles in chemistry, coupled with the identification of volcanic eruptions of known age (using ash chemistry and sulfate concentration anomalies preserved in the ice), allowed researchers to determine the age–depth relationship in cores from Summit, Greenland, to a precision better than 2% for the last 10 000 years (10 ky) and 5% for the last 50 ky. Precise determination of layer thickness and age also permitted the calculation of an accurate time series of accumulation (Figure 1).

Typical snow densities at the surface of an ice sheet are $\sim 300 \text{ kg m}^{-3}$, increasing to $\sim 900 \text{ kg m}^{-3}$ a few tens of meters below the surface. The zone of intermediate density, referred to

Figure 1 Depth versus age, measured annual layer thickness (λ) and calculated ice-equivalent annual accumulation ($\dot{b}$) in the GISP2 (Greenland Ice Sheet Project 2) ice core from Summit, central Greenland. The air bubble close-off depth (COD) is approximately at the intersection of $\dot{b}$ and λ .

as the firn, is a permeable layer through which atmospheric gases can move. As air channels in the firn become closed off, gases are isolated from the overlying atmosphere and are eventually trapped as air bubbles. Bubble close-off occurs at a density near 820 kg m^{-3} , which generally corresponds to a depth of 60–100 m. At a given depth, the age of the gas trapped within the ice is always younger than the ice itself because of advective and diffusive transport within the firn. The amount of time (eqn [1]) corresponding to the bubble-close-off depth (COD) is a nonlinear function of snow accumulation rate and temperature.

$$\Delta \text{age}(z) = t_{\text{ice}}(z) - t_{\text{gas}}(z) = t_{\text{ice}}(\text{COD}) \quad [1]$$

At high-accumulation sites like central Greenland ($\dot{b} > 200 \text{ kg m}^{-2} \text{ y}^{-1}$), Δage can be a few hundred years or less. At Vostok Station in central East Antarctica ($\dot{b} < 30 \text{ kg m}^{-2} \text{ y}^{-1}$), Δage is several thousand years. Several Antarctic ice core records have been dated indirectly by correlation with the layer-counted Greenland records, using variations in globally well-mixed trace gases as time markers (Figure 2). The major source of error in this cross-dating technique is uncertainty in the value of Δage .

Stable Isotopes and Temperature

Time-series of past temperature change are obtained from ice cores using the ratios of stable isotopes of water. The major features of the global distribution of water isotopes can be represented by a simple Rayleigh distillation approximation of the hydrological cycle that works particularly well at high latitudes. Seasonal variations in temperature (T) are reflected in the $^{18}\text{O}/^{16}\text{O}$ and D/H ratios of atmospheric water vapor and precipitation according to nearly linear relationships (eqns [2] and [3]).

$$\frac{d(\delta^{18}\text{O})}{dT} = \alpha \quad [2]$$

Figure 2 Concentrations of methane (CH_4) and isotopic ratio of molecular oxygen ($\delta^{18}\text{O}$ of O_2) from ice cores at Summit (GISP2), Greenland ($\bullet$, $\blacksquare$) and Taylor Dome, Antarctica ($\times$, $+$) between 10 and 20 ky ago. The oscillation in CH_4 between 13 ky and 11.5 ky is coincident with the Younger Dryas cold oscillation observed in paleoclimate records from around the North Atlantic region. The overall decrease in $\delta^{18}\text{O}$ of atmospheric O_2 (plotted on a reversed scale, by convention) reflects the increase in sea level from the influx of isotopically light (low $\delta^{18}\text{O}$) water from melting Northern Hemisphere ice sheets. Adapted with permission from E J Steig et al. (1998) Science 282: 92–95.

$$\frac{d(\delta D)}{d(\delta^{18}\text{O})} = 8 \quad [3]$$

The average value of α is about 0.7 ‰ K^{-1} . (‰ = parts per thousand; δ refers to the deviation in ‰ from the $^{18}\text{O}/^{16}\text{O}$ or D/H ratio of a standard, usually Standard Mean Ocean Water). Where temperatures are warm or snow accumulation rates are low, diffusion of water molecules within the firn layer will erase seasonal cycles after a few years to decades. Annual and inter-annual variations, however, are generally well preserved and provide a means of extending instrumental temperature records back in time. Regional or global climate events such as the Little Ice Age between c. AD 1400–1900, and the transition from the cold temperatures of the last glacial period, about 20 ky ago, to the current, Holocene interglacial period are clearly seen in the isotopic time-series (Figure 3). Also evident in Arctic ice cores are very rapid isotopic changes, known as Dansgaard–Oeschger (D–O) events after their discoverers. The calculation of temperature from isotope ratios is based on the assumption that the slope, α , of the δ/T relationship is constant. Calibration of the isotope paleothermometer has been accomplished using spatial gradients on instrumental time-series, and with paleotemperatures calculated from measured temperatures in liquid-filled boreholes, using geophysical inverse methods. The calibration results show that α varies by about a factor of 2 over glacial–interglacial time scales because of changes in the seasonality of precipitation, moist air mass transport trajectories, and ocean surface conditions. Where such changes can be quantified, $\delta^{18}\text{O}$ and δD may be considered reliable quantitative proxies for past temperature

Figure 3 Oxygen isotope ratios of water ($\delta^{18}\text{O}$) from the GISP2 ice core, Greenland, from 100 ky ago to the present. The transition from the highly variable glacial period to the relative stable Holocene interglacial occurs at ~ 11.5 ky. The most recent 11 ky are shown on an expanded scale.

change. Ocean surface conditions, specifically, can be investigated using variations in 'deuterium excess', defined in

$$d = \delta\text{D} - 8 \times \delta^{18}\text{O} \quad [4]$$

Deviations of d from the average meteoric water value of 10‰ reflect the difference in sensitivity to phase changes of δD versus $\delta^{18}\text{O}$. Ice core time series of d are used to identify the ocean source areas for polar and high-altitude water vapor, and to quantify changes in evaporation temperature and humidity at those source areas.

Trace Gases

Ice cores provide an essentially direct record of past concentrations of atmospheric gases. Depending on the magnitude of Δage , each gas sample analyzed typically represents an average of a few hundred years. Measurement of CO_2 from Greenland ice cores has been problematic because of the relatively warm temperature and high carbonate content of the ice. That CO_2

records from Antarctic ice cores are reliable is demonstrated by the excellent agreement with direct atmospheric measurements during the period of overlap (Figure 4). Over long time scales CO_2 is linearly related (correlation coefficient, $r^2 > 0.7$) to stable-isotope records of air temperature (Figure 5). Natural variations over the last 420 ky remained within 180–300 ppmv, well below the early twenty-first century value of > 370 ppmv. Analysis of data from multiple ice and ocean sediment cores indicates a lead of temperature over CO_2 of perhaps a few hundred years for glacial–interglacial time scales. However, the phase relationship appears to be nonstationary and its average value remains poorly known because of large uncertainties in Δage .

Concentrations of other atmospheric trace gases such as methane (CH_4) and nitrous oxide (N_2O) show long-term variations similar to those of CO_2 . Comparisons of records from ice cores in Antarctica and Greenland allows determination of changes in the inter-polar gradients of these gases, which reflects different biogenic production rates in the Northern versus Southern Hemispheres. Methane additionally shows rapid variations that correspond to the fast warming and cooling of the D–O events observed in $\delta^{18}\text{O}$ records. Measurements of $^{15}\text{N}/^{14}\text{N}$, $^{40}\text{Ar}/^{36}\text{Ar}$, and $^{84}\text{Kr}/^{36}\text{Ar}$ ratios reveal the preservation of thermally driven isotope ratio anomalies that permit independent calculation of the magnitude of temperature change and the value of Δage during these events. The results indicate that some of the D–O warmings were extremely rapid ($> 1^\circ\text{C}/\text{y}$) and of even larger magnitude (> 15 K) than would be predicted from $\alpha \sim 0.7\text{‰K}^{-1}$, and show that temperature leads CH_4 by no more than a few decades.

Another important set of data obtained from ice core air bubbles is the $^{18}\text{O}/^{16}\text{O}$ ratio of atmospheric molecular oxygen (O_2), reported as $\delta^{18}\text{O}_{\text{atm}}$ to distinguish it from $\delta^{18}\text{O}$ of ice. The primary control on $\delta^{18}\text{O}_{\text{atm}}$ is the isotopic composition of average surface ocean water ($\delta^{18}\text{O}_{\text{sw}}$), which in turn is determined to first order by global ice volume – the amount of water stored on land in the form of ice sheets and glaciers. Time-series

Figure 4 Carbon dioxide (CO_2) concentrations ($\circ$) from air bubbles in an ice core from Law Dome, Antarctica, for the last 1000 years compared with the direct measurements of atmospheric CO_2 (—) at Mauna Loa, Hawaii since AD 1959.

Figure 5 Concentrations of CO₂, δ¹⁸O of O₂, and methane (CH₄) in air bubbles and hydrogen isotopes ratios (δD) in ice from the Vostok ice core, central East Antarctica, for the last 420 ky.

of δ¹⁸O_{atm} from ice cores are used to tie ice core chronologies to each other and to marine sediment records of δ¹⁸O_{sw}. The connection between δ¹⁸O_{atm} and ocean water δ¹⁸O_{sw} is indirect, via photosynthesis and respiration by phytoplankton; there is a consequent variability in the lag between δ¹⁸O_{sw} and δ¹⁸O_{atm}, known as the 'Dole effect', of up to ~2000 years.

Aerosols and Soluble Gas-Phase Species

The major ions present in most ice cores are Na⁺, H⁺, Ca²⁺, Mg²⁺, Cl⁻, NO₃⁻ and SO₄²⁻. Typical concentrations are at the ppb (10⁻⁹) level. In coastal areas of the polar ice sheets, Na⁺, Cl⁻, Mg²⁺, Ca²⁺, and SO₄²⁻ represent > 80% of the ionic budget. Nitrate and non-sea-salt sulfate dominate the budget at more inland sites. All of these species show major variations that parallel those in stable isotopes and trace gas concentrations (Figure 6). Determining whether observed changes in concentration reflect changes in wet and dry deposition processes or real changes in atmospheric mixing ratios can be problematic. For example, a large fraction of the glacial-interglacial change in SO₄²⁻ concentrations probably reflects dilution by the twofold increase in snow accumulation rate at the beginning of the Holocene. The set of transfer functions describing air-to-snow relationships for all chemical

Figure 6 Concentrations of sodium, calcium, nitrate, and sulfate ions in the GISP2 ice core, Greenland, from 60 ky ago to the present.

species can be expressed as a formal mathematical inverse problem. Because of the high level of covariance in most ice core time-series, this problem must currently be considered under-terminated for most species. Nevertheless, significant changes in atmospheric mixing ratios have clearly occurred and are particularly large for terrestrially derived ions such as Ca²⁺.

Increases in terrestrial species reflect increases in the overall dustiness of the atmosphere due to enhanced continental aridity and aeolian transport during cold climate periods. This effect is amplified by increased wind speeds and the consequent greater efficiency of transport through the troposphere to the surfaces of glaciers and ice sheets. Specific source regions for continental dust have been identified through the use of isotopic and rare-earth element analysis of mineral grains preserved in the ice. Increased concentrations of marine-derived species in ice cores reflect increases both in transport efficiency and in biogenic production rates. More than 50% of SO₄²⁻ in inland Antarctic snow is derived from the oxidation of dimethyl sulfide, an algal waste product. The ratio of sulfate to methanesulfonic acid, an intermediate oxidation product that is preserved in the ice, has been used to identify biogenic versus nonbiogenic sources of SO₄²⁻. Changes in the biogenic contribution of SO₄²⁻ are of particular interest because of the role that sulfate aerosols play in climate forcing via modification of cloud radiative properties. Emissions from volcanoes are an important source of SO₄²⁻ concentration anomalies in ice cores; comparison with the

stable-isotope record of temperature provides strong independent evidence for the cooling effect of sulfate aerosols. In central Greenland cores, time-series analysis shows that geochemical variations can be resolved into two nearly orthogonal components that are dominated by marine and terrestrial species, respectively. The ratio of marine to terrestrial components is believed to reflect variations in the relative strength of meridional versus zonal tropospheric flow, possibly related to changes in the strength of the polar vortex.

Species such as hydrogen peroxide (H_2O_2), hydrochloric acid (HCl), and nitric acid (HNO_3), which have an appreciable vapor pressure at ambient surface temperatures, additionally complicate the interpretation of ice core geochemical records. While deposition rates are controlled by kinetic processes in clouds and at the snow surface, loss rates following deposition are dominated by the tendency toward equilibrium with the overlying atmosphere. Final concentrations archived in the ice core are determined by the extent to which equilibrium is reached. The approach to equilibrium depends on a combination of snow accumulation rate, temperature and, for photoreactive species, irradiance levels. Ambient oxidative conditions determined by hydroxyl radical ($\dot{\text{O}}\text{H}$) and ozone (O_3) mixing ratios also play a role. The measurement of multiple reactive and nonreactive species and their isotopic composition in ice cores offers a means for obtaining quantitative information on the oxidizing capacity of the atmosphere in the past.

Cosmogenic Radionuclides and Geomagnetic and Solar Variability

Rare isotopes produced in the atmosphere by cosmic rays, including ^{10}Be , ^{26}Al , ^{36}Cl , and ^{14}C , are all present in ice cores in measurable concentrations. These cosmogenic radionuclides (CRNs) are of interest as a means to extend the record of geomagnetic and solar variability beyond the instrumental and historical time periods and as a source of information on snow accumulation and atmospheric dynamics. Solar modulation of CRN production is reflected in variations in concentration that have dominant periodicities at ~ 11 years and ~ 90 years, and that closely track the record of atmospheric ^{14}C variations, independently derived from tree-ring studies (Figure 7). Over longer time scales, geomagnetic modulation may also be important in affecting CRN deposition rates. Differences among records from Arctic, tropical, and Antarctic ice cores can in principle be used to separate solar and geomagnetic modulation of CRN production, since the latter is unimportant at high latitudes. In practice, the difficulty of separating production variations from meteorologically influenced changes in deposition rate has prevented an unequivocal geomagnetic record from being obtained from CRN measurements. An exception is the large excursion observed in ^{10}Be and ^{36}Cl in several ice cores, which coincides with the Laschamp geomagnetic excursion 40 ky ago, when the field strength may have approached zero. Most other large changes in CRN concentrations reflect changes in snow accumulation rate. Assuming that production rates are approximately constant over time scales greater than those expected from solar variability (i.e. >1000 years), ^{10}Be can be used as an independent

Figure 7 Anomalies of ^{10}Be in an ice core from the South Pole compared with atmospheric ^{14}C anomalies from analyses of tree rings between AD 800 and 1950. The Δ notation refers to relative deviation in parts per thousand. Adapted with permission from E. Bard et al., *Earth and Planetary Science Letters* 150: 453–462.

variable in separating changes in atmospheric loading of other aerosol species from changes in precipitation scavenging and dry deposition efficiency. The assumption of constant production is reasonable in Antarctica, where limited meridional air-mass exchange prevents a significant amount of geomagnetically modulated, low-latitude-produced ^{10}Be from reaching the ice sheet surface. Because significant CRN production occurs in the stratosphere (about two-thirds of the total production), CRN can also provide information on past stratosphere/troposphere exchange processes. This has been accomplished qualitatively, using the magnitude of solar-modulated ^{10}Be variations, and the ratio of ^{36}Cl to ^{10}Be , which have different tropospheric lifetimes, as tracers of air mass origin. Radiocarbon (^{14}C) is a special case of CRN in ice cores because the predominant fraction is produced *in situ* by neutron activation of ^{14}N . Concentrations of ^{14}CO and $^{14}\text{CO}_2$ in air bubbles provide a determination of snow accumulation rate that agrees well with independent evidence.

The Causes of Ice Ages and Rapid Climate Change Events

Geochemical time-series from ice cores have had a profound influence on our understanding of climate change. Particularly important is the opportunity provided by ice cores to evaluate the characteristics of paleoclimate time-series in the frequency domain. The high-precision, independent dating achieved with ice cores has allowed a more rigorous test of Milankovich

theory than was previously possible with ocean sediment cores, and confirms that climate change exhibits significant power at orbital frequencies. The observation from the Vostok ice core that CO_2 varies approximately linearly with temperature addresses a critical problem for Milankovich theory, which is that the amplitude of solar insolation variations resulting from Earth's orbital changes is too small to alone account for the large magnitude of climate changes. At least 50% of the required amplification of small insolation changes over glacial–interglacial cycles can be attributed to observed CO_2 variations alone. The $\delta^{18}\text{O}_{\text{atm}}$ record shows a strong coherence with precession (~ 23 ky period) supporting the proposed linear relationship between orbital forcing and global ice-sheet volume.

Ice core data also demonstrate that large-magnitude climate changes have occurred in the past that are not related to Milankovich forcing. Although there is no evidence for rapid CO_2 changes in the past (variations originally identified in the Greenland Dye 3 ice core are now known to be artifacts), the D–O events clearly reflect real, rapid changes in atmospheric composition and dynamics. The D–O events are evident not only in $\delta^{18}\text{O}$ and CH_4 in Greenland ice cores, but also in dust and aerosol concentrations, and have been identified in ocean sediment cores from the North Atlantic region, from chemical tracers of deep water circulation, and from sea surface temperature. These events recur throughout the last glacial period with a nominal frequency of $1/1500 \text{ y}^{-1}$. There is considerable variation in the length of this cycle: in most data sets the spectral power of D–O events rises significantly above red noise only for bandwidths of several hundred years. On average, every fourth D–O event is associated with a coarse-grained ‘Heinrich’ layer in North Atlantic sediment cores. Heinrich layers reflect the transport of debris by icebergs from the margins of the ice sheets that covered much of Europe and North America during the last glaciation. Many paleoclimatologists believe that comparison of paleoclimate records from both hemispheres is a key to understanding the D–O events and their association with ocean thermohaline circulation and the dynamics of large ice sheets. Quasi-periodic climate changes with comparable timing have been identified in South American and Antarctic ice cores and Southern Ocean sediment cores, but these are generally smaller in amplitude and, with a few exceptions, do not show the rapid warmings characteristic of D–O events.

Natural Climate Variability and the Anthropogenic Impact on the Atmosphere

Ice core records provide an important baseline against which anthropogenic changes to the atmosphere can be measured. The high temporal resolution obtained with ice core geochemical and isotopic measurements has been used to extend records of the North Atlantic Oscillation and other important climate indices beyond the short period available from instrumental records. Arrays of ice cores covering the last 200–2000 years at annual resolution have been used to document the spatial patterns of interannual variability of both Arctic and Antarctic climate, for which instrumental data are particularly limited. On longer time scales, stable-isotope

records show that temperatures during the twentieth century were slightly cooler, on average, than during the peak warm intervals of both the last interglacial period (~ 125 ky ago) and the Holocene. A mid-Holocene warm period is especially pronounced in ice cores from northern Greenland and the Canadian Arctic. The ice cores provide little evidence, however, for temperatures as high as the last two decades of the twentieth century having occurred at any time in the past 100 000 years. Similarly, ice core records show that the background of natural variability in atmospheric chemistry is large. However, increases in most chemical species in the last 100–200 years appear to be unprecedented in magnitude and rate of change. Particularly clear signals of the anthropogenic impact on the chemistry of the troposphere include the following examples. Ice core measurements show that, relative to the AD 1900 value, concentrations of CH_4 have doubled, CO_2 has increased by 25%, and N_2O by 10%. In Northern Hemisphere ice cores, SO_4^{2-} concentrations increased by more than a factor of 4 between 1900 and 1970. This is in good agreement with the documented increase in SO_2 emissions from industrialized nations. Northern Hemisphere ice cores also document an overall decrease in SO_4^{2-} since 1980, probably reflecting abatement measures in the United States and Europe. Nitric acid deposition has similarly increased through most of the twentieth century and continues to increase. About 50% of the current NO_3^- deposited to Arctic snow can be attributed directly to anthropogenic NO_x emissions. Concentrations of heavy metals in Northern Hemisphere ice cores have increased since the late eighteenth century in parallel with growth in use since the industrial revolution. Isotopic studies have been used to identify source regions for these contaminants and show that United States emissions contributed about two-thirds of the deposition of lead from the atmosphere over Greenland until the late 1970s when the use of leaded gasoline declined. Finally, analysis of ice cores from several Arctic and temperate alpine locations shows that deposition rates of organochlorine pesticides remain at levels comparable to those of the 1970s when production and use was much higher than at present. The continued high concentration of these compounds in Arctic snowfall likely reflects their long residence times in soils.

Synopsis

A varve is a demonstrably annual marine or lacustrine sedimentary deposit. Varves provide a good method of dating past events. Because the deposition of sediment is related to environmental processes that are ultimately controlled by climate, the physical, chemical, or biological characteristics of a varved record provide a good proxy for climate and climate change.

Introduction

A varve is a deposit of sediment that can be shown to have accumulated during about 1 year. It is distinguished from deposits above and below by rhythmicity in one or more observable characteristics occurring in response to seasonal fluctuations of physical, chemical, or biological processes. The term derives from the Swedish word *varv*, meaning a layer, for example of stitches in a knitted garment or a lap around a racecourse. It was coined by de Geer (e.g., 1912) from his work on the Quaternary glacial-lacustrine deposits of Sweden (Figure 1(a)). The value of varves as climatic and paleoclimatic proxies lies in (1) demonstration that they are annual deposits and therefore may be used to determine absolute chronology, and (2) assessment that their sedimentary properties relate demonstrably to hydroclimatic processes. Although a varve is commonly defined as a couplet of light and dark sediment (Figure 1(b)) and so appears much like a tree ring, the spatial and temporal variability of environmental processes means that many varves are much more complex (Figure 1(c)). This often makes counting them more difficult, and so may make determination of chronology uncertain, but they offer a potentially rich source of information on regional climate as well as on specific events of weather, such as severe storms.

Formation of Varves

The depositional environment in which varves form is normally aquatic, although varves may occur subaerially, for example as a result of seasonally varying aeolian processes or snowfall (deposition of the crystalline mineral H_2O) in the accumulation areas, especially mid- and low-latitude alpine glaciers. In the latter case, melt or windblown dust in summer distinguishes depositions in each year as the snow transforms into glacial ice.

Aquatic varves have been described from many settings in lakes and the sea, but they all fall into one of three classes. *Clastic varves* normally consist of laminae of fine silt and clay-sized sediment deposited from suspension during periods of limited inflow of water and sediment, and periods of diminished processes of distribution in the water body. Coarse silt and sand layers are deposited in response to abundant inflow and vigorous circulation in the water body. Commonly, these couplets cannot be distinguished in fresh samples of wet

sediment, but on drying, the sand and coarse silt take on a light tone, while the hydrophilic clay remains moist and dark. Thus, with careful attention during drying, clastic varves are easily distinguished by eye (Figure 1(a)–1(c)), and photographic records are normally the best for analysis of thick varves, while thin sections are commonly used for submillimeter-sized varves.

The deposition of fine- and coarse-grained layers in a clastic varve is enhanced by processes within the water body. In lakes experiencing sediment-laden inflow, turbidity currents efficiently deliver bursts of sediment that are deposited nearly instantaneously as graded beds, and thus distinct layers are associated with each, often daily, event. Complex varves commonly form in this manner. The silty sand layers within the dark winter clay layers shown in Figure 1(c) result from the incursion of intense autumn and winter storms from the Pacific Ocean into the mountains. Snowmelt augmented by warm rain generates large floods that deliver bursts of coarser sediment to the lake, where turbidity currents efficiently transport them to the lake floor. The fine-grained laminae are deposited from settling through the water column. According to Stokes' law, a 1 μm diameter particle requires about 3 years to settle through a 100 m deep lake. Recent studies have demonstrated that the formation of small flocs in fresh water greatly increases settling velocity and allows the fine-grained sediments to accumulate during several months of quiet conditions, which are appropriate for the formation of the winter cap on a varve. In salt water, much larger flocs are formed and are removed from the water column in a few days to weeks. This may be a reason why clastic varves are uncommon in marine settings.

Biogenic varves form by the seasonal deposition of organic material derived from land (e.g., pollen production in spring) or originating in the water body itself (most commonly as blooms of diatoms or other aquatic organisms). Deposition of darker terrigenous organic residue and inorganic sediment separates the lighter biogenic laminae and so forms varves. These are the most common type of marine varves (Figure 1(d)); they usually form in basins with anoxic bottom water that prevents the establishment of a benthos that would bioturbate and destroy varves as they formed. Biogenic varves are also found in lakes, but here anoxic conditions are less important because the lacustrine benthos is commonly sparse or absent. Nevertheless, some of the best varve sequences occur in strongly stratified meromictic lakes that have almost no

Figure 1 (a) Section *in situ* of early Holocene glacialacustrine varves from Bergsbrunna, Sweden. These are part of the 12 000-year record first described by de Geer in the late nineteenth century. (b) Simple varves in a core of modern sediment from glacially dammed Ape Lake, British Columbia. Although these varves consist predominately of light and dark couplets because sediment input is in a melt-water pulse directly from the damming glacier and other sources of sediment are unimportant, variability within some varves can be distinguished. The dot indicates a crack formed during drying of the core. (c) Complex varves in a core from montane Lillooet Lake, British Columbia, where input is from large alpine glaciers up to 80 km distant, as well as from a variety of mountainside and valley-bottom sources. Interplay between maritime and continental air masses in the Cordillera contributes to the complexity. (d) Lithified Miocene marine varves in a hand specimen from the Monterey Formation of Southern California. The diffuse light-toned laminae are the result of annual diatom blooms. In each case, the varves are distinguished by tick marks to the right, and the scales are in 5 mm divisions.

currents at depth and where dissolved oxygen is low or absent. Anoxia also slows the decay of organic carbon that may form the distinctive lamina in some biogenic varves.

Chemogenic varves form in lakes as a result of the seasonal precipitation of salts, especially calcium carbonate, from a supersaturated solution created during summer when water temperature is high or when the uptake of carbon dioxide by aquatic vegetation is greatest. Coarse particulate carbonate normally settles through the water and becomes buried sufficiently quickly that most is not redissolved in the undersaturated cold-water deep in these lakes. In winter, the whole lake is sufficiently cold that carbonate does not precipitate, and even a small amount of terrigenous sediment is sufficient to produce a distinctive lamina to form a varve. Biogenic and chemogenic processes are more likely to form simple varves because they commonly occur only once per year, whereas processes associated with the deposition of clastic sediment are often of shorter duration and higher frequency.

Varve Chronology

Because the boundaries of a varve are normally placed at the most sharply distinguished transition between different forms of sediment (Figure 1), and because this usually occurs in spring or summer (associated with the onset of distinct processes of higher energy or activity), a varve does not correspond to a calendar year. As well, because the onset of seasonal events such as nival or glacial melt, monsoon rain, a diatom bloom, or precipitation of salts varies from year to year, sometimes by weeks or even by a month or more, neither does a varve represent exactly 1 year of deposition. These distinctions normally do not affect the use of varves as a measure of absolute chronology, but they may become significant when varves are used as proxy for particular seasonal events.

The value of varves as a dating tool depends on demonstration that their cyclicity is annual. Dates obtained from

varve counting may be related to independent evidence such as (1) radiometric dates, (2) the correlation of thickness time series with other proxies such as tree rings, coral bands, or glacial ice layers, (3) time-stratigraphic markers such as tephra, (4) measured or calculated rates of sediment accumulation, for example in sediment traps or from sub-bottom acoustic or seismic surveys, or (5) measured hydroclimatic variables. However, many accounts of varves depend only on the inference that strong, regular cycles must be annual, notwithstanding other regular cycles such as tides, daily temperature, rainfall and stream discharge, and even frequent storms that may also produce strong, regular cyclic effects. When the annual character cannot be demonstrated, cyclic deposits should be referred to as *rhythmites*.

Counting varves, like tree rings, is a simple procedure, although complex varves especially offer the likelihood of significant overestimation of age (Figure 1(c)). As well, if seasonal variation is sufficiently muted in some years, for example during a cool, dry summer when inflow of water and sediment is reduced, or precipitation of salts fails to occur, a varve may not be recognized, and thus, the age may be underestimated. Such errors can be reduced by comparison of time series records from a number of sites in the same or nearby water bodies, of other time series such as tree rings, or of independent counts of the same varve record by different observers. Techniques such as dot counting, which was developed by dendrochronologists, are now commonly used to determine varve chronologies.

The longest varve records, especially from marine sediments, extend over many thousands of years. Lacustrine records tend to be shorter, and fewer ancient records exist because lakes exist for shorter periods, varves tend to be thicker in lakes (Figure 1) and so fewer are recovered in a single core, and the heavy coring equipment available on large ships normally cannot be brought onto lakes. Nevertheless, a few long lacustrine records have been compiled by deep drilling from fixed platforms, or by linking the variations in thickness in modern lakes to those in progressively older lakes, in the manner that dendrochronologists link tree ring records from modern trees to ancient logs.

Varves as Hydroclimatic Proxy

Figure 2 suggests that there are a number of at least partially independent steps between weather and climate, and the record derived from varved sediment, each of these steps may limit the relation between these end members and so the value of varves as proxy. The production of terrestrial sediment by weathering and erosion involves processes that are at least as much a function of the geology of the parent material, geomorphic forces (e.g., colluvial activity and glaciation), and human factors (e.g., land use) as are the processes of climate. Exhaustion of large sediment supplies such as those produced by extensive glaciation may occur over thousands of years following retreat of the glaciers, and so the character of varves may change slowly and independently of climate. Fluvial transport sorts sediments spatially and temporally by size and composition, commonly storing materials for lengthy periods before delivery to the lake or sea. Hysteresis in the relation

Figure 2 Conceptual model showing the relation of a varve record to the ultimately controlling factors of weather and climate. The model is not comprehensive, and only the principal links are shown. Concepts are described in this article.

between water and sediment discharges further distorts the relation between hydrological factors and sediment transport in the short term.

Processes in a water body such as waves, the formation of chemical precipitates, circulation, and currents determine how sediment is distributed through the water body. Deposition of sediment is determined by processes such as settling from suspension, flocculation, gravity flow, and focusing of sediment from other parts of the water body, all of which have only weak links to climatic control. Diagenetic processes begin to alter the sediment immediately following deposition. These include dewatering and compaction so that earlier varves become progressively thinner, and chemical changes and physical disturbance occur. Lithification of sediment into sedimentary rock under high heat and pressure further changes the properties of the deposits.

Significant disturbance also occurs during recovery of the sediment from the lake or sea. Gravity corers compact and distort the sediment as they penetrate, for example by causing bowing down of the laminae due to friction with the side walls in varying amounts depending on the shear strength of individual laminae (Figures 1(b), 1(c), and 3). Piston corers may seriously distort sediment by suction or by contact with an unsecured piston during recovery. Improper transportation and storage may further disturb the sediment. During drying to best reveal the varves, shrinkage of the sediment leads to the formation of cracks and fissures (Figure 1(b)), and complete drying to prepare thin sections may cause larger cracks such as the large dark layers in the section shown in Figure 3. The use of X-radiography lessens this problem and, especially with marine varves, may produce superior results.

Despite all these limitations, many varve sequences do make excellent proxies for past general conditions of climate as well as for individual events of weather such as major storms. Most commonly, the time series of varve thickness is linked by

Figure 3 Varve record from Romulus Lake, Ellesmere Island, Nunavut. A photograph of a thin section of 40 mm of the core from 70.2 to 74.2 cm depth containing 68 varves is inset. It shows the variability in varve thickness and the disturbance (bowing) due to coring. The location of the lake is marked by an arrow on the inset map.

inference to climatic controls, as illustrated by **Figure 3**. Romulus Lake in the Canadian High Arctic has a concentration of salt three times that of seawater due to its isolation from the Arctic Ocean during isostatic uplift and due to the rejection of brine by growing permafrost in the drainage basin newly exposed by the uplift. The very strong stratification by density in this meromictic lake provides ideal conditions for the formation of varves. A relation to varying climate during the more than 1500-year record is inferred from understanding of periglacial conditions in the region. During the Medieval Warm Period centered on the eleventh century, higher temperatures and possibly greater rainfall caused the active layer to thicken and so melt the ice-rich permafrost beneath to produce major slope failures. This resulted in large pulses of water heavily charged with fine-grained marine silts and clays being delivered to the lake. Because this process is irregular in space and time, the variability in varve thickness is much greater during this period. Subsequent cooling of the climate, along with exhaustion of sediment as a result of these events, caused the permafrost to reestablish, the active layer to thin, and sediment delivery to decrease. Thus, the varves became thinner and the time series more regular. This culminated in the Little Ice Age of the eighteenth century, when conditions were coldest and sediment delivery least. A significant rise in thickness during the twentieth century may relate to conditions of global warming. If so, conditions equaling or exceeding those of the Medieval Warm Period may be expected in future. Similar, although less dramatic, effects have been reported from other arctic lakes as well as from ice-core records. It is in this convergence of evidence from a number of proxies that the strength of this method lies.

A second method for the use of varves as climatic proxy involves the development of a calibration based on the characteristics of varves, including thickness, stratigraphy, or composition, compared with instrumental records of weather and climate, or of observed processes of sediment production, delivery, and deposition. Statistical relations between, for example, varve thickness and mean annual or seasonal temperature or precipitation commonly do not produce

results in which more than 50–70% of the variability of varve thickness (the coefficient of variation, r^2) is accounted for by the measured variables of weather. Somewhat better results have been obtained in the relation between varve thickness and measured delivery of water or sediment to the water body because this involves fewer steps in the cascade (**Figure 2**). Studies of intraannual variation in the stratigraphy of varves have been linked to individual events of weather or climate. For example, each of the laminae in **Figure 1(c)** can be associated with discharge events in the inflowing river related to snow melt, glacial melt (and, by implication, summer temperature), or rainfall, including winter storms. Even though these and similar observed or implied relations have been determined in many studies, application to a varve time series from a different setting would be inappropriate because the relations are not universal. Even application of the calibration from modern varves to those that are from the same location but older than the instrumental record must be performed cautiously because the links shown in **Figure 2** are not temporally stable.

Introduction

Cloud radars (**Figure 1**) are active remote sensors that transmit at millimeter wavelengths and are particularly suited for determining the properties of nonprecipitating clouds such as stratus, altostratus, and cirrus. Millimeter-wave radars typically operate near 35 GHz ($\lambda = 8.6$ mm, Ka-band) or near 94 GHz ($\lambda = 3.3$ mm, W-band), which are frequency ‘window’ regions where absorption by atmospheric gases are at a minimum. Despite this, attenuation from atmospheric liquid and vapor is more of an issue for these short-wavelength radars than for longer-wavelength (centimeter scale) weather radars. Therefore, cloud radars often have range limitations of 20 km or less and are not suitable for observing conditions of moderate to heavy rainfall. The primary advantage of shorter-wavelength radars lies in their sensitivity to small ice particles and cloud droplets that can be two orders of magnitude smaller than typical raindrops. Some millimeter cloud radar systems are multiparameter; in other words, they transmit and receive electromagnetic waves at more than one wavelength or polarization.

Millimeter-wave radars are still primarily research instruments, typically unique prototypes designed and operated by university, government, or private research organizations. The rapid development of millimeter-wave cloud radars in the 1990s has been largely driven by the need to observe characteristics of nonprecipitating clouds in order to determine cloud impacts on global atmospheric radiation and consequences for climate predictions by large global climate models. In addition, scanning and airborne millimeter radars are used to make measurements necessary for understanding the physics of precipitation and the mechanisms by which precipitation forms. Cloud radars also are providing promising technologies for some operational applications, such as remotely sensing aircraft icing conditions (**Figure 2**).

Physics

Radar backscattering cross-sections (σ) for small particles vary inversely with the radar wavelength (λ) to the fourth power ($\sigma \propto \lambda^{-4}$). This physical property is the basis of the utility of short-wavelength radars for observing small particles and it enables cloud radars to utilize small antennas and to transmit peak power levels that are many orders of magnitude lower than those of weather radars. The beam width (θ) of a radar is related to the wavelength (λ) and the radar antenna diameter (A) by the relationship $\theta \propto \lambda A^{-1}$. This relationship means that, relative to antenna size, shorter-wavelength radars can obtain narrower beam widths; this, combined with short power pulses, allows for high-resolution observations (on the order of tens of meters) capable of resolving the fine-scale structure of clouds. With their lower power and small antenna requirements, cloud radar systems are ideal for portable systems that can be deployed in field experiments, in remote locations, as well as on ship, aircraft, and satellite platforms.

Received radar power (P) is measured in decibels (dB) referenced to 1 milliwatt (dBm) or $10 \log_{10} (P/\text{mW})$. The log scale is necessitated by the fact that returned power can vary over 8 orders of magnitude. The total received radar power is a function of three factors: distributed cloud target characteristics (effective reflectivity factor measured in dBZ_e referenced to $1 \text{ mm}^6 \text{ m}^{-3}$), the distance of the target(s) from the radar (r), and the radar constant (RC), which is based on the radar hardware characteristics (eqn [1]).

$$P(\text{dBm}) = Z_r(\text{dBZ}_r) - 20 \log r(\text{km}) - RC(\text{dB}) \quad [1]$$

This equation indicates that a smaller radar constant (RC) will result in more sensitive radar, since for a given atmospheric return (Z_r) at a given range (r), a smaller value of RC results in a stronger received signal (P). Thus, a critical goal of radar hardware design is minimization of the radar constant by optimally designing such factors as transmitted power level and antenna size. The radar reflectivity factor in dBZ_r can be converted to standard radar units of $\text{mm}^6 \text{ m}^{-3}$ using eqn [2].

$$Z_e = 10^{(\text{dBZ}_r/10)} \quad [2]$$

For Rayleigh scattering conditions ($D \ll \lambda$), the equivalent radar reflectivity factor of a population of hydrometeors is related to the diameters (D) of equal volume spherical particles (mm) and particle size distribution (N). For water droplets Z_r is given by eqn [3] and for ice particles by eqn [4], where ρ_0 is the ice particle bulk density in g cm^{-3} . These two equations are the basis for obtaining cloud microphysical properties from radar reflectivities.

$$Z_e = \int_0^\infty N(D) D^6 dD \quad [3]$$

$$Z_e = 0.2 \int_0^\infty N(D) [D \rho_0^{0.3333}]^6 dD \quad [4]$$

Figure 2 Use of cloud radar to sense aircraft icing conditions. Figure courtesy of Brooks Martner.

Typically, cloud radars also measure small Doppler shifts between the transmitted and received signal, which enables the calculation of the radial speed of cloud hydrometeors away from or towards the radar. Velocity measurements can be achieved with a precision on the order of 5 cm s^{-1} ; this is precise enough to be useful in measuring the fall velocities of ice crystals or cloud droplets as well as the turbulence characteristics of clouds. Some systems also record the complete Doppler spectra, in other words, the frequency distribution of Doppler velocities of the billions of hydrometeors within each radar sampling volume. Others record only the width of the Doppler spectrum in order to reduce the size of the collected data set.

History

One of the earliest meteorological uses of millimeter-wave radars was by the US Air Force, which operated 35 GHz radars at airbases as aids to aviation operations and forecasting in the 1960s. These non-Doppler systems successfully determined bulk cloud geometry, for instance cloud layer altitudes; however, these systems were eventually decommissioned owing to repeated failures with hardware. Some of the systems and parts from the systems were transferred to university research groups, but in general, the late 1970s and early 1980s were a period during which work with millimeter-wave radars declined. In the early 1980s, advances in solid-state, low-noise electronics inspired a number of research groups to develop both surface-based and airborne cloud radars and to demonstrate their usefulness for elucidating the properties of non-precipitating and lightly precipitating clouds. In particular, scanning and depolarization capabilities were added to greatly increase the utility of these systems. In addition to the engineering advances, innovative techniques for combining radar and lidar measurements, as well as radar and radiometer measurements (microwave and infrared), were developed that have led to the ability to estimate values of important microphysical and optical cloud properties. These include, but are not limited to, crystal/droplet size, concentration, water content, and cloud optical depth. Radars with polarization capabilities provide additional information for determining cloud crystal or droplet shape and orientation, and by inference, phase. The 1990s were also the first decade when a few millimeter-wave radars began operation on a continuous and long-term basis for climate research.

Meteorological Applications

Cloud Structure

Nonprecipitating and lightly precipitating clouds are predominant features of the Earth's physical environment; however, quantitative measurements of seemingly straightforward features such as cloud height and thickness and the number of cloud layers have historically been extremely difficult to obtain. Without radar measurements, the primary alternative for observing these important cloud properties are detection of cloud bases from laser ceilometers operating at airports and weather stations, cloud tops estimates from satellite radiance measurements, and qualitative visual

estimates by human observers of the heights of clouds and number of layers. In contrast, cloud radars provide comprehensive and detailed information on the geometrical morphology of clouds within the constraints of attenuation at one end of the detection scale and nondetection of extremely small cloud hydrometeors at the other. In interpreting cloud boundaries, it must be considered that there is often no significant difference in radar reflectivities between cloudy regions and adjacent regions of precipitation; these regions must be distinguished by the change in structure of the Doppler velocities, the Doppler spectra, or with additional measurements as might be provided by another instrument such cloud base ceilometer or lidar. Figure 3 shows an example of simultaneous, complex, multilayered cloud scenes from operational cloud radars in Barrow, Alaska (top panel) and in Lamont, Oklahoma (bottom panel) for a 24-hour period on 29 July 1998. The labels on the figure indicate a number of interesting features detected by the radars including cirrus, melting-layer bright bands, light drizzle, altostratus, boundary-layer stratus, and insects.

Cloud Water Contents and Crystal and Droplet Size Determination

A number of techniques that utilize cloud radar measurements, either alone or in combination with additional measurements from lidars or radiometers, can be used to retrieve information on cloud properties. The term 'retrieve' in this context indicates the process of theoretically inferring physical cloud microphysical and optical aspects (such as cloud water contents, crystal or droplet sizes, and cloud optical depths) from some combination of directly measured quantities (such as radar reflectivity, Doppler velocities, radiometric brightness temperatures, and lidar backscatter). These methods can be divided into those that use radar data only, those that use radar and radiometer data, and those that use radar data in combination with lidar measurements.

The earliest radar-only retrieval methods were based on empirical relationships between radar reflectivity factor and ice water content (IWC) or liquid water content (LWC) of the form given in eqn [5], where the a and b coefficients were typically based upon physical regressions from either *in situ* cloud ice crystal or droplet measurements from aircraft or from ground observations.

$$\text{IWC or LWC} = a \times (Z_e)^b \quad [5]$$

Although useful, these methods tend to have a wide range of variability in values of the a and b coefficients, depending on the specific individual cloud data sets that are used to determine the coefficients.

The next generation of retrieval techniques for ice cloud parameters used radar reflectivity measurements to obtain a cloud layer average Z_e , and infrared radiometer measurements of the brightness temperature of downwelling radiation in the $10 \mu\text{m}$ to $11.5 \mu\text{m}$ spectral band to calculate cloud optical depth. Using the fact that layer-mean reflectivity and the brightness temperature are proportional to the sixth and the second moments of the cloud particle size distribution, respectively, cloud layer averages of crystal sizes can be estimated. The optical depth calculation can also be used to

Figure 3 Simultaneous multilayered cloud scenes produced by operational cloud radars in Barrow, Alaska (top panel) and Lamont, Oklahoma (bottom panel). Figure courtesy of Brooks Martner.

determine a specific value for the coefficient a , and a fixed value can be reasonably assumed for the coefficient b , which in general has a smaller degree of variability (between 0.55 and 0.75). Eqn [5] can then be applied through the depth of the cloud to calculate profiles of ice water content. From these profiles of ice water content, mean particle diameters are calculated by using an assumed relationship between ice crystal size and bulk density. Additional adjustments to this technique involve the use of the microphysical profiles to calculate downwelling solar irradiances with a radiative transfer model, comparison to measured values, and iteration to achieve consistency with the additional solar measurements.

A drawback to the techniques that incorporate infrared radiometer data is that retrievals are limited to situations in which ice clouds are optically thin and are not observationally obscured by intervening liquid clouds which obfuscate the radiometer measurements. The need for retrievals that can be applied to a broader range of cloud types and multilayer situations has led to the most recent development in radar-based retrievals that utilize radar Doppler velocities. In this method, Doppler velocities are averaged over time periods sufficient to average out the effect of vertical air motions to yield estimates of crystal fall speeds. The crystal fall speeds can then be used to estimate crystal sizes and ice water contents.

The development of retrievals for liquid clouds has paralleled that of ice clouds, with estimates of optical depth from infrared radiometers being replaced by measurements of column-integrated liquid-water path from microwave radiometers. The original empirical relationships of the form described by eqn [5] were followed by techniques that used the profile of radar reflectivity, in combination with microwave radiometric liquid-water path, to determine a profile of liquid-water contents based on the assumption that the drop size distribution was lognormal and the droplet concentration was constant through the depth of the cloud. A second technique uses *a priori* data sets from aircraft collected in an ensemble of clouds similar to those for which the retrievals are to be

performed. From these, empirical regressions are determined between both radar reflectivity and liquid-water content, as well as between radar reflectivity and droplet sizes. This second technique can be used when microwave radiometer data is unavailable or it is unclear which cloud layers or levels contain the liquid layers. Figure 4 shows an example of cloud-water contents that have been retrieved for a low-level liquid water cloud using radar and microwave radiometer, and an overlying upper-level ice cloud using radar-only measurements of reflectivity and Doppler velocity.

Another completely different approach to retrievals of cloud properties is to use cloud radar in combination with cloud lidar. Radar and lidar retrieval techniques use Mie scattering theory and accounts for partial attenuation of lidar signals. This enables theoretical calculation of radar and lidar backscatter cross-sections, and the ratios of the backscatter cross-sections can be then computed as a function of particle size. These computed curves can be used to interpret measured radar and lidar cross-sections in terms of ice crystal sizes.

Note that the methods described here have been developed for either all-ice clouds or all-liquid clouds. In the real environment many clouds have mixed phase elements. Since these cloud types have different microphysical and radiative characteristics than the simpler single-phase clouds, their characterization remains a priority research issue for the cloud radar research community.

Crystal and Droplet Shape and Orientation

Electromagnetic radiation consists of perpendicular electric and magnetic fields that can be directionally oriented or 'polarized'. By convention, the polarization of an electromagnetic wave refers to the direction of the orientation of the electric field. Cloud hydrometeors will depolarize (change the orientation) of an electromagnetic wave when it is scattered back to the radar receiver as a function of hydrometeor shape (with implications for cloud phase), aspect ratio, orientation, and

Figure 4 Ice-water and liquid-water content of clouds determined using a combination of radar-only and radar-radiometer retrieval techniques.

bulk density. Thus information on these cloud parameters can be obtained by examining how polarization of the received signal has changed with respect to the transmitted signal. To measure this change, the radar must transmit and/or receive in two separate polarizations, allowing the calculation of depolarization ratios. Such radars are referred to as polarimetric or dual polarization radars. Various polarization states ranging from linear to circular are possible, depending on how vertically and horizontally polarized pulses are mixed in the transmission scheme. Common schemes include utilization of linear depolarization ratios (LDR), circular depolarization ratios (CDR), differential reflectivities (ZDR), and the more recently developed 45° slantwise depolarization ratios (SLDR). These are summarized in Table 1, along with power ratio ranges that can result from different types of cloud targets.

Theoretically, perfect spheres (such as very small cloud droplets) will have no depolarizing effect on electromagnetic waves, resulting in a depolarization ratio of $-\infty$, while scatterers with large length-to-width aspect ratios (such as chaff) will be highly polarizing, with depolarization ratios approaching 0 dB. Meteorological targets such as drizzle, dendrites, plates, columns, and graupel will have depolarization ratios in between these values. It should be noted that, in practice, it is very difficult to generate or measure electromagnetic waves with perfect circular or linear depolarization, and the lower limit for depolarization ratios is determined by the inability to perfectly isolate the power leakage between different polarization states generated by the radar. This lower limit is referred to as the antenna cross-talk limit, or antenna cancellation ratio

(denoted as $-\infty$ in Table 1) and will vary as a function of the type of polarization chosen. Therefore, in practice, it is optimum to choose polarization states for which a maximum dynamic range can be achieved since rather than $-\infty$, the true lower threshold will be a system limited finite value.

Because certain ice crystal types have preferred fall orientations, the polarization ratios observed by radar for the same target type can also vary as a function of the elevation angle at which the radar views the cloud. For this reason, scanning dual-polarization radar through a cloud can be a very powerful tool. Figure 5 shows 45° slantwise depolarization ratios as a function of radar elevation. This figure clearly demonstrates the utility of this radar polarization scheme for determining hydrometeor type.

Platforms

The comparatively low power requirements, small antenna size requirements, and robust electronics of millimeter-wave cloud radars enable the design of systems that are suitable for deployment in portable containers and on vehicles, aircraft, and ships. New engineering designs have also resulted in unattended systems that can operate continuously, and an increasing number of such systems are collecting data around the globe both in long-term atmospheric monitoring programs and in short-term field experiments. Present plans indicate that the first space-based cloud radar will be launched sometime between 2004 and 2010. Such space-based cloud radars, together

Table 1 Common radar polarization schemes

Target	Linear depolarization ratio (LDR) [10 log (Z_{HV}/Z_{HH})]	Differential reflectivity (ZDR) [10 log (Z_{HH}/Z_{VV})]	Circular depolarization ratio (CDR) [10 log (Z_{LL}/Z_{LR})]	45° Slantwise depolarization ratio (SLDR) [10 log ($Z_{(135)(45)}/Z_{(45)(45)}$)]
Cloud droplets	$-\infty$ dB	0 dB	$-\infty$ dB	$-\infty$ dB
Ice crystals	$-\infty$ to -10 dB	0 to 4 dB	$-\infty$ to -7 dB	$-\infty$ to -7 dB

Note: for each Z_{XY} , Z is the power, X is the received polarization, and Y is the transmitted polarization, where H = horizontal linear, V = vertical linear, L = left-hand circular, R = right-hand circular, 135 = linear rotated 135° from horizontal, 45 = and linear rotated 45° from horizontal.

Introduction

The incoherent scatter radar (ISR) technique is a powerful ground-based tool used to measure various properties of the ionized part of the upper atmosphere called the ionosphere. All radars transmit radio waves at a target and receive much weaker waves generated when electrons, the lightest charged component of the target matter, accelerate in response to the incident waves and reradiate the signal. Reflection and scatter are terms used to describe the reradiation, depending upon the degree and nature of the organization of the electrons in the target. Incoherent scatter returns come from free electrons in the ionospheric gas, or plasma, usually with a strong influence from the ions. ISRs can be used to measure electron and ion temperatures and velocities, and the number densities of the electrons and the various ions. ISR has remained a useful technique for ionospheric studies during the last 40 years, because a complete, accurate, and elegant theory describes the spectrum of the scattered signal, and because inexpensive and easily implemented digital signal processing makes the use of new radar techniques practical and allows new and better data analysis methods. Data analysis consists of comparing measured spectra with model spectra, adjusting the model parameters for a good match using nonlinear least-squares fitting. The primary task of ISRs is the global study of the effects of energy inputs into the ionosphere and upper atmosphere, that is, solar radiation and particles entering along the Earth's magnetic field lines from above, and energy, often in the form of waves, from the denser atmosphere below. ISRs verify many aspects of the behavior of the ionospheric plasma, including plasma instabilities generated naturally and artificially. ISRs also make measurements in the middle atmosphere, and can function as MST (mesosphere–stratosphere–thermosphere) radars in the lower atmosphere.

The required hardware is large: one or more antennas, 30–300 m in diameter, and a powerful transmitter, 1 MW or more, capable of transmitting for several percent of the time. Most radars are monostatic, using the same antennas for transmission and reception. Each ISR is the result of different compromises in design, trading away the less needed characteristics in order to lower the cost. The Arecibo radar (18.3° N, 293.2° E) obtains a very high sensitivity at 430 MHz by using a fixed spherical dish 305 m in diameter constructed in a sinkhole in Puerto Rico. Energy focuses to a line rather than a point as with a parabolic antenna, and the original design used a long line feed antenna. Today, a Gregorian feed with secondary and tertiary reflectors is used to correct the spherical aberration. With such a large antenna the feed is moved rather than the dish, with zenith angles of 20° attainable at Arecibo. The Jicamarca observatory in Peru (−12.0° N, 283.1° E) uses a large array of dipoles operating at 50 MHz to obtain a similar

sensitivity. It has a limited range of pointing angles nearly perpendicular to the magnetic field and is used to study the electrodynamics and other features of the ionosphere at the magnetic equator.

Radars requiring full sky coverage use movable parabolic dishes, and accept lower sensitivity as a result of the smaller antenna. The Millstone Hill facility in Massachusetts, USA (42.6° E, 288.5° N) operates at 440 MHz and has two parabolic dishes, one fixed in the vertical direction (68 m) and the other (46 m) rapidly steerable over most of the sky. The Sondrestrom facility in Greenland (67.0° N, 309.0° E) operates at about 1100 MHz and also uses a steerable parabolic dish (32 m). This radar has moved from the Stanford Campus to Alaska and then to Greenland in response to the needs of the scientific community. These four radars form a longitudinal chain operated under the CEDAR (Coupling, Energetics, and Dynamics of Atmospheric Regions) program of the US National Science Foundation (NSF).

The EISCAT (European Incoherent Scatter) Association, a consortium of six European countries and Japan, operates the newest facilities. These are 931 MHz radar with transmitting and receiving facilities in Tromsø, Norway (69.6° N, 19.2° E) and receiving sites in Kiruna, Sweden, and Sodankylä, Finland, a so-called tristatic system. The Tromsø site also has a monostatic 224 MHz system using a cylindrical paraboloidal antenna with mechanical steering in one plane and electrical pointing by means of phasing in the other plane. The newest EISCAT radar is located in the Svalbard archipelago on the island of Spitzbergen (78° N, 20° E) and has two parabolic dishes. The Institute of Ionosphere in Kharkov, Ukraine, operates a facility at 150 MHz with a 100 m fixed vertical dish and a 25 m steerable dish. The Institute of Solar-Terrestrial Physics operates a radar near Irkutsk (53° N, 103° E) in Russia (Siberia) which steers by changing the frequency between 154 and 162 MHz. The EISCAT, NSF, and Kharkov radars frequently operate together on 'World Days' that allow global studies of the ionosphere and space weather events. Originally designed for middle atmospheric studies, the MU radar near Shigaraki, Japan, has regularly been used in the ISR mode in recent years.

Elementary Description: Operation and Scattering Mechanism

Figure 1 shows the range–time diagram for an ISR spectral measurement in which the radar emits a pulse of length T that illuminates the electrons at range h_0 during a time interval T_0 , and at h_1 during a later time interval T_1 . The overlap of these time intervals is not a problem when the requirements for range resolution are modest.

Figure 1 (a) A range–time diagram in which a pulse of length T is transmitted, illuminating electrons at range h_0 for time interval T_0 and range h_1 for time interval t_1 . The substantial overlap in time might or might not be a problem. (b) The electrons at h_1 have apparently random locations and velocities. The radar is sensitive to the component along the line of sight (z axis). (c) The Maxwellian probability density function associated with the speed of the electrons and the Gaussian function associated with the line of sight component. (d) The signal at time t_s is the sum of that from many electrons with random phase. The radar analyzes the rectangular projections of the sum. Part (a) also shows two short pulses p_0 and p_1 . The signal at each time is the sum of narrow ranges resulting from both pulses.

Nearly all of the power passes through the ionosphere, but a small amount scatters from the electrons. Consider N electrons in a small range increment around h_1 . They move with speeds distributed according to a Maxwellian distribution and with apparently random directions. The received radar signal is the sum of the very small signals scattered from all the individual electrons, and consideration of the phase path length for each electron from the transmitting antenna and back to the receiving antenna gives eqn [1] for the return signal.

$$S(t) = \sum_{i=0}^{N-1} a e^{i(\omega_0 t - k r_i(t))} \quad [1]$$

where S is the summed signal; a comes from the radar equation and depends on factors such as the power and antenna gain of the radar, the distance to the electrons, and possibly the polarization of the waves; ω_0 is the angular frequency of the radar, $k = 4\pi/\lambda$ is the scattering radar wave number for backscatter for a radar wavelength λ ; and r_i is the line of sight distance from the radar to the i -th electron. The receiver circuitry removes the rotation of the signal at the rate ω_0 so that the time variation in the signal is due to the motion of the electrons. It is apparent that eqn [1] is the spatial Fourier transform of the scattering medium along the line of sight, providing a convenient abstraction from the actual charge distribution. If there is only one electron with constant velocity along the radar line of sight, then the change in the phase of the received signal is uniform in time, and S is a sinusoid like the transmitted signal, but Doppler shifted to a new frequency.

If the electron velocities are uncorrelated, the phase angles in the sum are random, and the time-averaged power from the volume is just N times the power from a single electron, a quantity easily computed from elementary electromagnetism. The cross section of a single electron is given by $4\pi r_e^2$, where

$r_e = 2.8 \times 10^{-15}$ m is the classical electron radius, and so an electron looks like a target of 9.85×10^{-29} m. If one illuminates a cube 20 km on a side that contains an electron number density 1×10^{12} m⁻³, the total cross section is 7.9×10^{-4} m², equivalent to a sphere with a radius of 1.6 cm. Also the received radar signal is a noise-like process, and so the information about the medium is contained in the average properties of the process, the average total power, and the distribution of this power in frequency. If each electron moves with constant velocity during the time it is illuminated by the radar signal, then the spectrum is the bell-shaped Gaussian function. This follows from the Maxwellian distribution of electron speeds determined by T_e , the electron temperature, and m_e , the mass of the electron, because the velocity distribution of electrons determines the distribution of power at the corresponding Doppler shift. Actually, the electrical interaction between the ions and the electrons narrows the spectrum and determines the pulse length T required for adequate frequency resolution. Nevertheless, the Gaussian electron spectrum, as well as similar ones associated with the ions, is important in the complete analysis.

Measurement Techniques

Techniques for improving the resolution use short pulses or a modulated pulse, often with a constant transmitted amplitude, but a binary phase pattern (0° and 180°). The goal is to obtain statistical estimates of the spectrum as a function of range that are as accurate as possible and have sufficient range resolution. The signal power must be large and the receiver and sky noise small, and the number of independent samples from the noise-like signal must be large so that measurements of its

average properties are accurate. In addition to the use of a modulated pulse, sometimes transmissions occur on different frequencies at different times during the pulse, or even on several frequencies at once.

If the range resolution obtained using a pulse length of T , set by frequency resolution requirements, is not good enough, one solution is to use sequences of two or more short pulses, but then the average transmitted power decreases. It is also possible to use modulated long pulses, explained here using a simple analogy. If only the total power and not the spectrum is of interest, then obtaining the performance of a short pulse from a properly modulated long pulse by decoding the signal is easy, and a very similar method allows decoding of the set of lag profiles used in computing the spectral estimates. A lag profile is the product of the signal and a delayed version of the complex conjugate of the signal, while the set comprises lag profiles of all useful delays. This section analyzes pulse compression of the signal, the double (short) pulse technique, and the use of pulse compression on lag profiles to measure the spectrum with good range resolution.

A rectangular radar pulse of length T and unity peak power has the same total energy as one of length T/M and power M . The power spectrum of the shorter pulse contains a lot more energy in the higher frequencies. For the long pulse to give the same resolution as the short one it must have the same energy at the higher frequencies and a practical, but approximate, method to produce this is to use phase modulation, such as the Barker code (Figure 2). Then the major difference between the two pulses is the relative phases of the sinusoidal components of their spectra. Changing the phase of the spectrum of the signal corresponds to a linear filtering operation in the time domain, and the long pulse can be converted to a short pulse, or 'decoded' in this way. The received signal before decoding consists of copies of the code, one for each target, shifted by the range to the target and added. The addition of the target signals is linear, and so it can be decoded in the receiver after the target signals add, obtaining the same results as operating on each signal individually. The result is almost like using a short pulse of high peak power, as the simulation in the right-hand part of

Figure 2 shows. It used matched filter decoding, which has the best signal-to-noise ratio, but it also has small false echoes, or sidelobes, at a level of about 1% of the main echo or lobe.

The target must remain close to stationary while illuminated by the coded pulse if the decoding is to occur accurately. For lower atmosphere radars where the spectrum of the scatter is very narrow, decoding can extend over multiple pulses, allowing the use of complementary codes that have canceling sidelobes. In the ionosphere, the spectrum widens as the temperature rises and lighter ions dominate. In the topside of the ionosphere, pulse compression is less practical.

The power spectrum of a random process such as ionospheric radar signals contains the same information as its Fourier transform, the autocorrelation function (ACF). The ACF is the sum of lag products obtained by multiplying samples of the process from one time with the complex conjugates of those from later times. Just as the radar signal at a particular time is the result of scatter from a range of heights depending upon the length of the radar pulse and how it is modulated, a lag profile is made up of lag products from a similar range of heights. The set of lag profiles for all delays contains all possible information about the ACF.

Figure 3 shows the results of a simulation where the model ionospheric density increases linearly with altitude and has two very narrow, closely spaced layers of electron density enhancement, a situation that might occur in the E region. If the transmission is two short pulses spaced by three times their width, where the pulse and layer spacing correspond, as in Figure 3(a), two of the four signals from the layers are coincident, and the overlapping signal is twice as high as the others, demonstrating the simple addition of powers resulting from the lack of correlation of the scatter from different ranges. The noise rejection bandpass filter spreads the signal in height gives the waveforms pointed shapes.

Figure 3(b) shows the lag profile with a delay equal to the layer spacing, showing only one return from each layer just as required. Although Figure 1 shows that the returns at times t_0 and t_1 from short pulses p_0 and p_1 are each the sum of scatter from two heights, they have only one height in

Figure 2 A radar can transmit the uncoded long pulse, but needs to transmit a pulse 13 times shorter with 13 times the peak power and the same total power. This is very expensive; instead it modulates the long pulse with the Barker code and uses signal processing techniques to get nearly the same results. The modulated pulse must have a spectrum as close as possible to that of the short pulse. The simulation at the right shows that the signal from five narrow targets looks almost the same with the short pulse and the Barker-coded pulse.

Figure 3 (a) The power profile resulting from a pair of short pulses with spacing three times their width and a pair of thin layers with corresponding spacing. (b) The lag profile for a spacing of 3; there is only a single return from each layer! This desirable result occurs because scattered signals from different heights are not correlated. (c) and (d) Comparison of the performance of the double pulse technique and the random codes technique (coded long pulse) for a case with high sky and system noise. The latter has less noise on the profile and obtains all of the different lags at once, resulting in more than 50 times better time resolution.

common. (A diagonal line downward-to-the right defines the heights and times of scattered signal entering the receiver simultaneously.) Thus the product of the two returns has only one term involving the same height, and only it has correlation. However, the terms that do not correlate still contribute random clutter, and thus increase the noise on the profile. It is possible to transmit the two pulses on orthogonal polarizations at the Jicamarca radar, eliminating the extra noise, but it is inevitable with more than two pulses. The filter used to reduce the effect of receiver and sky noise also spreads the signals in time, introducing a spread of delays into the lag profile. Shortening the pulse or correction during analysis of the data eliminates this problem.

Varying the pulse spacing allows different lag delays to be measured, giving all the necessary information about the random process. This simple technique provides excellent measurements, but it is slow because sampling of each lag occurs sequentially, and also the pair of short pulses generally uses only a small fraction of the available transmitter power. Special sequences using three or more pulses partially address both of these problems. Several ambiguity-free lag profiles occur simultaneously from these multiple pulse sequences, which have the property that each of the several delays measured by pairs of pulses in the sequence occurs only once. However, multiple pulse sequences are still sparse, even when interleaving several sequences on different frequencies, a technique used at the EISCAT facilities.

Suppose a long phase-coded pulse is transmitted where the length of a baud, the shortest section of constant phase, is equal to the short pulse and the total length is 16 Bd. The lag profile for a delay of 3 Bd contains lag products at one time covering a height range of 13 Bd, and the lag products from one height are present for a time of 13 Bd. All of the many products involving more than one height have zero average values owing to lack of correlation, ignoring the effect of the noise rejection filter. (The simulations do include this small effect.) The lag profile is a sum of lag products from all heights but all with the same delay, and this suggests that one should decode the lag

profile just like the Barker-coded signal. However, the sequence of signs given by the product of the transmitted code with itself shifted by 3 Bd determines the code, and thus the code is different for each delay. That is, if a code is present, new codes can be generated by multiplying it by itself shifted by some integral number of bauds. The ACF of each of these new codes has a central peak and sidelobes. Any code that has sidelobes nearly as low as a Barker code is a good code. Unfortunately, there is no code which generates good codes for each shift. This deficiency can be made up by using a sequence of codes such that the generated codes for each shift have sidelobes which cancel or tend to do so, like the complementary sequences described above. The sequence can be as long as needed, since only the stationarity of the ACF rather than the signal is important. One useful solution is to use a different random code on each transmitted pulse. Products of shifted random sequences are also random sequences, and so the sidelobes are random and approach zero as more pulses are used, as shown in Figure 4. Exact cancellation is not necessary since it is not possible to remove the clutter power, but only to remove its systematic effect. However, it is remarkable that short sequences of codes with no more members than twice the number of bauds can achieve perfect cancellation of the average value of lag product sidelobes. These sequences, called alternating codes, are found with very clever computer search techniques. Both these techniques – alternating codes and the random codes or coded long pulse technique – are in regular use. They give nearly identical results when used correctly, and the choice of technique depends upon practical considerations.

Figure 3(c) and 3(d) shows the improvement of these techniques over the double pulse when receiver and sky noise dominate. Part (c) shows the double pulse measurement for an accumulation of 1000 transmitted pulses. Each of the other delays requires the same number of transmissions. Part (d) shows the results for the random codes, and there are two differences affecting the relative speeds. First, all the different delays are available simultaneously with the random codes; and second, the random noise is lower than the double pulse.

Figure 4 The various waveforms associated with the coded long pulse technique. In the receiver, the signal from one height (a) appears to be multiplied by the code (b), resulting in a modulated signal (c). If the code (b) is shifted by 3 Bd and multiplied by itself, then the resulting code (d) determines the lag profile (e). Decoding with the code (d) gives lag profile (f). The central peak is the signal that is wanted; the rest of the profile is undesirable clutter that becomes relatively small with summation over many radar pulses.

As a result of both of these factors, the random codes are more than 50 times faster than the double pulse.

It is very complicated to determine the exact relative merits of the techniques when neither clutter nor noise dominates. However, it is clear that in the clutter-dominated case they are all nearly the same, with the noted exception for the double pulse at Jicamarca.

The Incoherent Scatter Spectrum

The elementary analysis above ignored the electrostatic interaction among the various components of the plasma; the interaction between the electrons and ions is very important. **Figure 5** shows several plots computed by means of a program that includes this interaction. Part (a) shows a sequence using the Arecibo $\mathbf{k}$ vector, with the electron density n_e increasing by a factor of 2. Each plot is the ratio of the spectrum and its associated n_e , so that an invariant shape would give identical plots. The lowest, 25 cm^{-3} , gives a spectrum that is almost exactly Gaussian, but there is a very small unresolved narrow feature at zero frequency. However, as n_e increases to easily measurable values, power shifts into the narrow feature and the Gaussian shape is lost. Part (b) shows the frequency scale expanded by 100 times to resolve the narrow feature. As n_e increases, the spectral ratios become identical. It would appear that all of the power has shifted to the narrow feature, called the ion line, with constant shape; actually there is a small amount of power in the plasma line, a very narrow feature at the plasma resonance frequency (about 9 MHz for $n_e = 10^6 \text{ cm}^{-3}$). Fast electrons produced by photoionization or other causes enhance this line, making it a useful complement to the ion line.

Part (c) shows the ion line also; here, $n_e = 10^6 \text{ cm}^{-3}$ for all cases but T_e varies as T_i is held constant. As T_e/T_i changes from 1 to 8, the spectrum becomes more peaked; the location of the peak depends upon the temperature of the electrons and the mass of the ion. Part (d) shows the effect of changing the ion mass. Lighter ions result in wider spectra with similar shapes;

O^+ , He^+ , and H^+ have masses of 16, 4, and 1, respectively. With two or more ions present, the shape differs from the sum of the spectra for the single ions, particularly if the ion masses are similar.

One of the several approaches to constructing a theory containing the electron-ion interaction uses the Nyquist theorem, familiar to electrical engineers for determining the random noise level in lossy circuits but also useful for plasma fluctuations in a generalized form. The different species (electrons and each kind of ion) all have admittance functions that combine to form the spectrum of a sort of 'circuit.' The dressed particle approach calculates the effect of each particle on each of the other species, and so the total effect of a particle is the sum of its intrinsic charge and the induced charges. Finding the induced charge requires a perturbation solution of the Vlasov equation. The motion of the individual charges determines the effect of the intrinsic charge, like the simple Gaussian electron spectrum found above and by a similar method for the ions. It turns out that consideration of the induced charges gives integrals over the velocity density function that are very similar to the ones for the intrinsic charge, and so in effect these single species spectra combine in a fairly simple way to give the complete incoherent scatter spectrum. The ion line is scattered from ion acoustic waves at the thermal level, while the plasma line is scattered from Langmuir waves, possibly enhanced above the thermal level by photoelectrons or other causes. It is also possible to include the effects of the magnetic field and most types of collisions are also possible.

The Debye length is an important parameter in the equation for the spectrum. It defines a scale length that determines the behavior of the plasma. For smaller lengths, the thermal energy of the plasma is sufficient to keep the species independent, but for longer lengths the electrical interactions are strong enough to tightly couple the species. Thus the Debye length increases with temperature, but decreases with the concentration of charges, qualitatively explaining the spectra of **Figure 5(a)** and **5(b)**.

The Maxwellian velocity distribution is established by collisions between pairs of particles, either of the same or of

Figure 5 Various incoherent scatter spectra. Parts (a) and (b) show the ratios of the spectrum with the corresponding electron density. Part (a) shows that the wide Gaussian spectrum occurs only for very small electron densities. At higher densities that can be easily seen with a radar, the power shifts into a narrow line, resolved in (b). Part (c) shows what happens as T_e changes while $T_i = 1000$ K and $n_e = 10^6$ cm⁻³. Part (d) shows the effects of various ratios of different ions with the other parameters as in part (c) with $T_e/T_i = 1$.

different species. Collisions are so infrequent that they have no significant effect on the spectrum of the scatter in the F region for most ISRs, but this is not so at lower altitudes in the E and D regions. The effect on the single species spectrum is simple to understand in principle, but it can be difficult to compute with

good accuracy. When a particle changes direction and speed frequently in a time interval in which its progress along the radar line of sight is small, as measured by the phase change of the signal, its apparent progress is slowed. In the limit of many collisions, it is like the so-called random walk (or drunk sailor's walk) in which the progress from a starting point is proportional to the square root of time rather than linear. Thus the spectrum is narrowed. There is a second effect resulting from the sudden changes in the speed along the radar line of sight that is very much like modulating the carrier of an FM radio station. This causes the energy to spread to higher frequencies, but at a reduced power level. Figure 6(a) shows the net effect for four different values of ion-neutral collision frequency for the Arecibo case using the Bhatnagar-Gross-Krook (BGK) collision model.

Figure 6(b) shows the effect of the Earth's magnetic field using $\mathbf{k}$ vectors for the Jicamarca radar. The gyroradius for electrons is significantly smaller than the radar wavelength, and so the only effective motion is along the field lines. As the radar looks more closely to perpendicular, an electron has to move very far before it significantly affects the phase of the radar signal. This takes a long time, and so the electron single species spectrum becomes narrow. The ion spectrum normally determines the width of the incoherent scatter spectrum since it is narrower than the electron spectrum, and so as the angle moves from parallel toward perpendicular there is very little effect at first. However, eventually the electron spectrum becomes narrower than the ion spectrum

Figure 6 (a) The effects of collisions on the spectrum for four different ion-neutral collision frequencies. The plot indicates ionospheric regions where the collision frequencies are typical. Part (b) shows how the backscatter spectrum varies as the angle between the radar $\mathbf{k}$ vector and the magnetic field approaches perpendicular. These curves are only approximately correct since the effects of Coulomb collisions are not included.

and takes control as the ions lose their influence on the electrons. The fact that the electrons must move so far before the phase of the radar signal changes has another surprising effect discovered recently. The effects of Coulomb collisions on an electron due to other electrons and ions are significant, a rare case where collisions matter in the F region. These collisions narrow the spectrum by about a factor of 2 for an angle of 0.25° , and strongly affect T_e/T_i to more than 2° from perpendicular.

Synopsis

Wind profiling radars measure very high frequency or ultra high frequency radiation scattered by the clear atmosphere from around 70 m to 20 km altitude in the stratosphere and troposphere, and from 70 to 90 km in the mesosphere. The scattering mechanisms include turbulence, Fresnel scattering, and scattering from free electrons. Wind profiles are typically measured with a vertical resolution of 75–300 m every 15–30 min, with accuracy of $1\text{--}2\text{ m s}^{-1}$. The signal power and spectral width of the radar echoes contain information on atmospheric layers and turbulence, respectively. Radars are used in networks and in conjunction with other instruments for many applications.

Introduction

Radar systems were originally developed to detect solid targets, so the potential of radar for detecting precipitation in the atmosphere was realized very early on. Less obvious was the potential application of radio waves scattered by the air itself – such mysterious echoes were dubbed ‘angels’ in the early days. Unlike the scattering of light waves, which results from direct interaction between the photons and individual air molecules, the scattering of radio waves depends on irregularities in the refractive index of the air on scales comparable to the radar wavelength, typically centimeters to meters. Turbulence plays a prominent role in generating such structures, allowing radar to be used for remote sensing of turbulence. Furthermore, the irregularities move with the mean flow of the air, so by measuring the Doppler shift of the scattered radiation the radar can measure the wind speed component along the beam. Combining wind speed measurements in three (or more) directions provides a measure of wind velocity, and in the continuous measurement of vertical profiles of winds this technique has found its most common application. Uniquely, these radars can continuously measure the vertical component of wind, a parameter of particular interest to meteorologists.

The use of very high frequency (VHF) (usually around 50 MHz) and ultra high frequency (UHF) (around 400–500, 915, or 1215 MHz) radars to measure vertical profiles of winds and turbulence in the atmosphere originated in the early 1970s. Mesosphere–Stratosphere–Troposphere (MST) radars were developed from instruments originally designed to study the lower ionosphere. To reach these altitudes a large radar system is required, with an antenna array typically around 10^4 m^2 and powerful radio transmitters; the Aberystwyth MST radar in the United Kingdom, shown in [Figure 1](#), is a typical example. As the technique has developed, however, its main applications have been found in operational meteorology, where the required altitude coverage is restricted to the troposphere and lowermost stratosphere (Stratosphere–Troposphere radars) or to even lower altitudes. Boundary layer profilers, measuring in the bottom 2–3 km of the atmosphere, are now commercially available from a number of manufacturers

worldwide (e.g., [Figure 2](#)). These rely on UHF frequencies, bringing down the cost of the radar and permitting readily transportable (trailer-mounted) systems. Despite the differences in size and operating frequency, however, the same underlying principles apply to all these radar systems.

Scattering Mechanisms

The refractive index of air may be approximated as follows:

$$n = 1 + 10^{-6} \left(77.6 \frac{p}{T} + 3.75 \cdot 10^5 \frac{e}{T^2} \right) \quad [1]$$

where p is the dry pressure in hPa, e is the partial pressure of water vapor in hPa, and T is the temperature in K. The term in brackets is usually termed the refractivity N .

In the lower atmosphere, up to ~ 20 km altitude, fluctuations in atmospheric density (manifest in the temperature and humidity terms) determine the scattering cross section. Above this height scattering from the neutral atmosphere is too faint to be detected, but in the lower ionosphere the much larger cross section of free electrons results in a second region of radar echoes, extending in practice from about 70 to 90 km. Mesospheric echoes have a lower altitude limit determined by electron density and an upper limit determined by viscosity, which increases with height, eventually limiting the inner scale of turbulence (the boundary between the inertial and viscous scales) to values greater than the radar wavelength (see below).

The classic interpretation of UHF and VHF radar echoes is that they arise from turbulence in the atmosphere. In the presence of a large-scale vertical gradient in refractive index, turbulence acts to bring air parcels with different temperature and humidity into close proximity, setting up a random field of fluctuations in refractive index covering the entire spectrum between the inner and outer scales of turbulence. If the outer scale (thickness of a turbulent layer) is much larger than the radar wavelength, Bragg scattering applies – the scattering cross section results entirely from the Fourier component with wave vector $2\mathbf{K}$, where $\mathbf{K}$ is the wave vector of the incident electromagnetic wave. This means the radar is sensitive to fluctuations

Figure 1 The Mesosphere–Stratosphere–Troposphere radar at Aberystwyth, Wales, UK (52.4° N, 4.01° W). This radar has operated continuously since 1997, measuring wind profiles between 2 and ~16 km. It operates at 46.5 MHz, with 400 Yagi antennas covering an area 100 × 100 m.

on the scale of half the wavelength – around 3 m in the case of VHF radars and 10 cm in the UHF case.

When turbulence fills the radar range gate, the radar reflectivity η is related to the refractive index structure constant c_n^2 by:

$$\eta = 0.38 c_n^2 \lambda^{-1/3} \quad [2]$$

where λ is the radar wavelength. c_n^2 may be further expressed as:

$$c_n^2 = a \varepsilon^{-1/3} K M^2 \quad [3]$$

where a is a constant (approximately equal to 3.3), ε is the turbulent energy dissipation rate (in W m^{-3}), K is the eddy

diffusion coefficient, and M is the potential refractive index gradient, derived using quantities (potential temperature θ and specific humidity q in kg kg^{-1}) that are conserved in adiabatic vertical displacement (see Vaughan and Worthington, 2000 for further details).

$$M = -77.6 \cdot 10^{-6} \frac{p}{T} \left(\frac{\partial \ln \theta}{\partial z} \left[1 + \frac{15\,500\,q}{T} \right] - \frac{7750}{T} \frac{\partial q}{\partial z} \right) \quad [4]$$

In this model the received radar power P becomes $\text{Pr}^2 \propto c_n^2 \lambda^{-1/3}$, with r^2 accounting for the inverse square law in radiation intensity from scattering (r is the range), and the

Figure 2 UHF radar (1.29 GHz) built by Degreane and operated by the UK's Atmospheric Measurement Facility. It has three panels, pointing to the vertical and 15° off vertical, and is mounted on a trailer, which can be towed to different locations for field campaigns. The UK Mesosphere–Stratosphere–Troposphere radar is shown in the background.

constant of proportionality depending on the radar transmitted power, antenna area and gain, receiver efficiency, and assumptions made about the turbulent scattering processes.

Such is the conceptual simplicity of the Bragg scattering theory that many radar studies, particularly at UHF wavelengths, assume that the echo power is a direct measure of turbulent intensity. Early in the development of VHF radars, however, it became obvious that this could not explain all the observations. Almost all VHF echo profiles were found to be at least mildly aspect sensitive, in other words the echo power decreased rapidly as the radar beam was directed away from the zenith. Furthermore, the spectral width of the echo power was very narrow. To explain this, the theory of Fresnel scattering was proposed. Here, the vertical profile of refractive index is considered to comprise ‘sheets,’ i.e., step changes over vertical distances commensurate with the radar wavelength but horizontally coherent over the radar beam width. If these sheets are very numerous, and distributed randomly in the vertical, Bragg scattering will again apply in that the Fourier component matching $2K$ will be preferentially scattered. In this case, the radar reflectivity η is given by:

$$\eta = (\delta r)^2 \frac{F(\lambda)^2}{16} M^2 \quad [5]$$

where δr is the range resolution of the radar and $F(\lambda)$ is a function relating refractive index variations on the small-scale to the

large-scale gradient measurable, for instance, by a radiosonde. Unlike echoes from turbulence, these echoes are specular because of the sheetlike nature of the scattering irregularities. Evidence for the existence of sharp gradients in refractive index on small vertical scales has come from balloon flights with specially designed temperature sensors, and a correspondence has been shown between the distribution of such steps and echo power from a nearby VHF radar. However, the horizontal extent of the sharp gradients is not known, and the nature of specular reflection of electromagnetic radiation remains controversial.

These two models of reflectivity are best considered as limiting cases, with the actual mechanism at any time depending on the state of the atmosphere and the radar wavelength. At VHF, specular echoes predominate so that the Fresnel model is most appropriate in most conditions. However, the echoes are rarely purely specular, and the degree of anisotropy (rate at which echo power decreases with zenith angle) is highly variable. Models of anisotropic turbulence have been proposed to explain this phenomenon, but so far none of them challenges the conceptual simplicity of the two described above. At UHF wavelengths, particularly in the convective daytime boundary layer, turbulent (isotropic) scatter dominates and echo power is related to turbulent intensity – but UHF profilers measure almost as effectively at night as in the daytime, depicting in particular residual layers of turbulence as shown in Figure 3.

Figure 3 Example of measurements from the boundary-layer profiler shown in Figure 2, located at Achern in Germany on 24 June 2007. Note the growth of the convective boundary layer during the morning, shown both in signal-to-noise ratio and spectral width, and the residual layer between 3 and 2.5 km at night.

Both VHF and UHF wind profilers detect scattering from precipitation, but at VHF this echo seldom exceeds the clear-air backscatter. The reverse is the case at UHF, where because of the shorter wavelength Rayleigh scattering from droplets and ice particles is much stronger. As with conventional rain radars, a bright band may be observed at the melting level at UHF. Vertical velocities measured by these radars during precipitation events are those of the falling particles – but because the particles are moved horizontally by the wind, the derived horizontal velocities match the wind components. Indeed, this can present an advantage by extending the vertical coverage of the radar. In clear air, a UHF profiler seldom measures above ~ 3 km; during the passage of a front, for example, winds may be measured up to 10 km or even higher. At VHF, heavy convective rain events can (because of the size of the droplets) provide both a clear air and a particle peak in the Doppler spectrum, both of which can be measured separately if required.

In contrast to UHF radars, where precipitation always enhances the echo power, stratiform or frontal rain has the effect of reducing VHF echo power (e.g., Figure 4). In such events, the droplets are too small to be observed, and the reduction in power most probably occurs because the falling raindrops ‘wash out’ structure in refractive index on the scale of the radar wavelength. The function F in eqn [5] linking M

measured on the scale of a radar range gate and the smaller-scale fluctuations that scatter the radio waves is clearly different in clear and precipitating air.

Whereas suitable fluctuations in refractive index in the troposphere and lower stratosphere are present throughout the day (permitting continuous wind measurements), those in the mesosphere are more sporadic, since free electrons in this part of the atmosphere generally occur in daytime and the echoes are patchy in space and time.

Wind Measurements

The most common method for measuring winds with radar is the Doppler beam swinging technique. With this technique, the radar beam is emitted and received by the same antenna, and is sequentially directed vertically and at off-vertical angles close to the zenith (e.g., at four orthogonal azimuths directed at 5 – 15° to the zenith). By measuring the Doppler shift of the received echo relative to that transmitted, and combining the velocities derived along the different radial directions, a profile of the three components of wind may be constructed. Typical dwell times along each radial direction are 10 – 20 s, so a profile may take several minutes to measure. The technique therefore implicitly assumes both horizontal uniformity of the wind

Figure 4 Example of measurements from the VHF radar at Aberystwyth for the period of 18 h on 4 September 2011 to 2359 h on 5 September 2011, showing: (i) passage of a cold front between 18 and 24 on 4th (ascending layer of high wind shear), (ii) passage of warm front on the 5th (descending layer of high wind shear), (iii) mountain waves (large values of vertical velocity lasting several hours), (iv) convection (short-lived maxima in vertical velocity near 0 h), (v) the tropopause (black crosses), (vi) suppression of radar power by rain (6–8 and 16–19 h, below 6 km).

within the volume containing the various beams, and stationarity in time over the measurement cycle. In the troposphere and lower stratosphere, the horizontal scale corresponds to a few kilometers, and in the mesosphere to a few tens of kilometers. This is generally sufficient for meteorological measurements but for mesospheric applications an alternative technique, called spaced antenna drift, is sometimes used. Here, one transmitted beam is coupled to a number (three or more) of receiving antennas, and wind velocities calculated through correlation analysis of the measured signals. Further discussion of this technique (which has also been used occasionally for tropospheric and lower stratospheric radars) may be found in [Hocking \(2011\)](#).

The distinguishing physical feature of wind profiling radars compared to the popular perception of radar is the absence of a steerable dish. The long wavelengths needed to receive clear-air echoes preclude mechanical steering other than in exceptional cases, so the basic construction becomes an array of antennas to which the electromagnetic radiation can be fed from one or more transmitters. The array shown in [Figure 1](#), for example, comprises 400 Yagi antennas over an area 100×100 m, which are fed with five transmitters located in the building next to it. The typical peak power is 160 kW with a two-way half-power beam width of 2.2° at 46.5 MHz. For a VHF radar of this type, beam steering is achieved by changing the phase of the transmitted wave across the array. In this case, the phase is changed by switching lengths of cable into the transmitter line, but a more flexible arrangement is to use distributed (lower power) transmitters, each serving a few antennas, where the phase can be controlled in software. The large array, and the need to protect the sensitive receiver from the transmitted pulse, means there is a dead time in measurement with these systems corresponding to around 1–2 km altitude; wind measurements are not possible at altitudes much lower than this.

For UHF radars of gigahertz frequencies and above, a much smaller array is needed to achieve the same beam width and the dead time between transmission and receiving is less; wind measurements are possible above around 70 m with these radars. Phase switching may be used to direct the beam as at VHF, or a different approach may be used – fixed panels containing arrays of antenna elements directed vertically and at orthogonal azimuths off vertical. An example of such a system is shown in [Figure 2](#). Otherwise the basic principles of UHF and VHF radars are very similar.

An ideal wind profiler will have high vertical and temporal resolution and high accuracy. In practice, a number of factors limit these qualities, and there are trade-offs between them. Vertical resolution is limited by the duration of the transmitted pulse, which in turn is determined by the radio bandwidth available to the radar. Regulatory authorities are reluctant to issue licenses for wide-bandwidth transmitters, so the pulse length normally used is around 1 μ s, corresponding to a vertical range of 150 m (at UHF shorter pulses can be used, giving around half this vertical range). In radar terms, resolution refers to the ability to distinguish two hard targets a certain distance apart, which is not applicable for a continuous medium, so this vertical range is often used as a measure of the vertical resolution. It should be kept in mind that the actual resolution will depend both on atmospheric conditions and on the application defining that resolution.

A device commonly used to improve signal-to-noise ratio while preserving range resolution is pulse coding. Here, a longer pulse is emitted, with the phase of the electromagnetic wave being flipped by 180° at (say) 1 μ s intervals. Complementary codes have been devised, which allow the full range resolution of the radar to be recovered by decoding this information in the receiver while preserving the power advantage of the longer pulse.

To derive a radial wind value in a given range gate from a wind profiler, the basic method is to measure the echo signal in phase and in quadrature with the local oscillator at time intervals $\Delta\tau$. A time series of these measurements is then converted into a spectrum using Fourier analysis, and the first moment of the spectrum used to measure the Doppler shift (the complex signal values are needed to allow the Fourier analysis to distinguish motion toward and away from the radar). Clearly the Nyquist frequency, determining the maximum unambiguously measurable radial wind velocity, $V_{\max}$, is $f_N = 1/2\Delta\tau$ cycles per second. Since the Doppler shift is $2V/\lambda$ for radial wind speed V , this corresponds to $V_{\max} = \lambda/4\Delta\tau$. A VHF radio transmitter is typically operated at a pulse repetition frequency of around 1 kHz; any higher and there is the possibility of echoes from one pulse being contaminated with high-altitude echoes from the previous one. With $\lambda = 6$ m, $\Delta\tau = 1$ ms corresponds to $V_{\max} = 1500$ m s $^{-1}$ – far in excess of any conceivable atmospheric velocity. This provides an opportunity to use coherent averaging – averaging over tens to hundreds of pulses – to improve signal-to-noise ratio and provide values of $\Delta\tau$ closer to 0.3 s likely to be needed in practice.

The length of the Fourier transform determines the resolution of the derived spectrum (again by the Nyquist theorem), which is one constraint on its accuracy. A longer time series provides a better resolved spectrum – but this introduces another error, arising from the assumption of stationarity. Measuring a sample of signal returned over ~ 10 s (a typical value used in practice) and deriving a single spectrum from it assumes that the atmosphere above the radar does not change its properties during this time. Of course this is not the case in practice, and the choice of operating parameters is a compromise between the desire for resolution and good signal-to-noise ratio, and the desire to measure a representative wind.

At UHF, the value of $\Delta\tau$ needed to keep $V_{\max}$ to a reasonable value is much smaller, and much shorter time series are needed for the same velocity resolution. Pulse repetition frequencies can also be higher since echoes from the high atmosphere may be neglected. Here, incoherent averaging is often employed to improve signal-to-noise ratio – averaging of a number of successive spectra before calculating the spectral parameters. Also common in UHF radars is the use of different modes – short pulses for detailed measurements at low levels and longer pulses to extend the vertical coverage.

Once the spectrum is calculated, the derivation of atmospheric parameters is in principle simple. Given a bell-shaped spectral feature occupying, say, a fifth of the measured spectrum, its integral (zeroth moment) gives the echo power, its first moment the radial velocity and its second moment the spectral width – after first subtracting the noise power derived from the remaining four-fifths of the spectrum. In practice matters are rarely this simple. Ground clutter, for example,

affects all radars to some extent so that points around zero Doppler shift must be removed from the analysis – thus rendering the radar unable to measure very light winds. For UHF radars the problem is much worse – these receive echoes from birds, swaying power lines, and other moving targets that contaminate spectral values well away from zero. At least the radar echoes from well-developed boundary layer turbulence are close to Gaussian in shape, and amenable to interpretation as a mean velocity with some variance around it. VHF echoes from the free atmosphere often look nothing like a Gaussian spectrum, frequently being multimodal.

For this reason useful winds from both VHF and UHF wind profilers involve some degree of averaging. Although a raw wind measurement may be made every 1–2 min, reliable winds are usually provided every 15–30 min. At UHF, consensus averaging algorithms are used, to eliminate the frequent wild outliers derived from the raw spectra. At VHF, simple averaging of the winds is usually enough. With this proviso, the accuracy of radar wind profiles when compared to near-coincident radiosondes is found to be in the range 1–2 m s⁻¹. Systematic errors also affect the measurements, particularly at VHF where the anisotropy of the echoes from the atmosphere effectively draws an off-vertical beam closer to the zenith than its nominal position. Corrections are normally made for such errors, but uncertainties of a few percent remain. For example, regular comparisons are made at the UK Met Office between wind profiles assimilated into the operational forecast model and the background field, both as a bias and root mean square (rms) difference. They find that radiosondes and the Aberystwyth MST radar wind profiles have almost identical biases (<1 m s⁻¹) and rms differences (2–3 m s⁻¹) with respect to the model.

Signal Power and Turbulence

Equations [2] and [5] both contain the term M^2 – whatever the model, the radar echo power is proportional to the square of the potential refractivity gradient. Therefore, there is a close relationship between the measured echo power and sharp gradients of humidity and potential temperature (eqn [4]). Indeed, eqn [4] shows that these two terms are of opposite sign – so that maximum power is expected for layers where $\partial\theta/\partial z$ is positive and $\partial q/\partial z$ is negative. These conditions are routinely met at the tropopause and the boundary layer top, both of which can be accurately identified in VHF and UHF profiles, respectively, provided the atmospheric feature is itself well defined. Examples of each are shown in Figures 3 and 4, respectively. Detailed comparisons of radar power with M^2 derived from radiosonde profiles show that the relationship is qualitative rather than quantitative with a great deal of scatter around the underlying correlation. Nevertheless, it remains the case that the information content of VHF echo power profiles is yet to be fully exploited.

At UHF, the echo power during daytime clearly identifies the mixed layer, with its characteristic growth and decay (Figure 3). Given the unambiguous turbulent scattering filling the radar echo volume, it is possible therefore to derive c_n^2 from the power, if the radar system constants are known (i.e., the radar is calibrated). However, in most cases wind profiling

radars are not calibrated since this is not necessary for the wind measurements that are their primary product. Quantitative information on turbulence is therefore derived from the spectral width: the second moment of the spectrum.

Turbulence within a volume of air creates a spread of instantaneous velocities, the magnitude of which depends on the strength of the turbulence. This is detected by the radar as a range of Doppler velocities – a broad echo spectrum. Equations have been derived linking the turbulent energy dissipation rate ε and the eddy diffusion coefficient K to the radial velocity variance measured by the radar, $\overline{V'^2}$:

$$\varepsilon = f_1 \overline{V'^2} \omega_b \quad [6]$$

$$K = \frac{f_2 \varepsilon}{\omega_b^2} \quad [7]$$

where ω_b is the Brunt–Vaisala frequency and f_1 and f_2 are constants. There is considerable debate about the values of these constants; Hocking (2011) recommends $f_1 = 0.27$ and $f_2 = 0.25$.

Unfortunately, turbulence is not the only effect that can broaden a radar echo spectrum, the most prominent competing effects being beam broadening and shear broadening. Beam broadening is a result of the finite angular width of a radar beam; for a nominally vertical beam, for example, the edges will extend a degree or more away from the vertical. A horizontal wind in these circumstances will have a component in the radial direction at the edge of the beam, causing a broadening of the measured (vertical) Doppler spectrum. Shear broadening is more direct: a gradient in the horizontal velocity along a beam produces a range of radial wind components within the scattering volume unrelated to any turbulence. Methods have been devised to evaluate and remove these effects, but since they are usually the dominant source of broadening such methods are only partially successful. The exception is in the daytime boundary layer, where the strong and generally isotropic turbulence means that it dominates the spectra. At VHF, turbulence can only normally be detected in deep convective clouds or in thin layers of shear-driven turbulence, most commonly found around the jet stream.

Mesospheric Measurements

Above about 25 km, the echo power from the molecular atmosphere becomes too weak to detect even with the most powerful radars. This remains the case throughout the stratosphere, until the lower altitudes of the ionosphere are reached. Here, scattering from electrons provides an echo allowing VHF radars in particular to be used to study the altitude region between 70 and 90 km. The basic technique is no different to that already described, but particular features of the mesospheric echoes need to be taken into account.

Of particular importance for mesospheric studies is the availability of turbulent fluctuations in electron density. The inner scale of turbulence is around 5 m at 80 km, which means that UHF wavelengths are well into the viscous subrange in the mesosphere and should not be strongly scattered. At VHF, however, the radar measurement scale of ~3 m can lie in the

inertial subrange and so provide measurable scatter. Between 70 and 80 km, sporadic VHF echoes can be measured from the sunlit atmosphere throughout the year – free electrons in this part of the atmosphere are produced by short-wavelength solar illumination and do not persist into the hours of darkness. Wind measurements derived from these echoes enable studies of gravity waves, planetary waves, and tides that dominate the dynamics of the mesosphere.

Considerations of the inner scale of turbulence suggest that VHF echoes should not be measured much above 80 km. By contrast this is where the strongest mesospheric echoes by far are found! These are the polar mesospheric summer echoes (PMSEs), which occur at high latitudes around midsummer. At this time of year, the mesopause is at its coldest and indeed the polar summer mesopause can reach 140 K, easily the coldest region of the Earth's atmosphere. These cold temperatures result in noctilucent clouds of tiny ice particles that, like PMSEs, can extend to temperate latitudes around the solstice. Observations of PMSEs show that the echoes are highly variable, both in altitude and in time, and although generally coexisting with noctilucent clouds they are not exactly correlated with them. Typically, they are found as thin layers of high echo power between 80 and 90 km (e.g., Figure 5), most prominent at midday. Several theories for producing PMSEs have been advanced but this is still an area of active research.

Applications of Wind Profilers

One of the particular strengths of radar wind profilers is their ability to measure the vertical component of the wind. This finds its most fruitful application in studies of convection and atmospheric gravity waves: small-scale processes with vertical velocities of order 1 m s^{-1} or greater. By contrast, synoptic-scale vertical velocities, typically of order 1 cm s^{-1} , are very difficult to measure with wind profilers – for example, given a maximum radial velocity of 5 m s^{-1} ($\Delta\tau = 0.3 \text{ s}$), a 512-point Fourier transform would be needed just to provide a raw resolution of 1 cm s^{-1} , requiring a dwell time of around 2.5 min – far longer than the 10–20 s normally used. Even with adequate resolution, very long averaging times ($\sim 10 \text{ h}$) are required to remove the smaller-scale features, and experience

shows that systematic biases arise, which render the final result questionable.

Gravity Waves

Gravity waves are ubiquitous in the free atmosphere where the static stability is generally positive, and the full spectrum of gravity wave motions, from the Brunt–Väisälä period to the inertial period f_i , may be measured with a VHF radar. Of particular importance are mountain waves – standing gravity wave patterns forced by topography, and occurring in the majority of synoptic environments even over small hills. Air flowing through these patterns oscillates vertically at a frequency at or close to ω_b , but the pattern itself changes much more slowly – with a typical timescale of several hours as the synoptic environment itself changes. Consequently, a VHF radar fixed in one location will measure a pattern of vertical motion that changes over this timescale – which must not be confused with genuine synoptic-scale vertical motion. VHF radar measurements of mountain waves are valuable for testing numerical models of wave propagation and for identifying layers where the waves break – typically at altitudes where the wind component along the wave propagation vector is zero (a so-called critical layer). Enhanced spectral width in such layers is a measure of turbulence as mentioned above.

At the other end of the gravity wave spectrum are inertia–gravity waves – waves where the Coriolis acceleration causes individual air parcels to trace out ellipses in the plane of propagation of the wave. Because of the low frequency, these planes are almost horizontal, and inertia–gravity waves are detected using the horizontal wind components rather than the vertical. These waves are very common in midlatitudes, especially in the lower stratosphere where maxima and minima in wind components descend over time, and may be tracked over many hours (or even days in extreme cases). They are associated with jet streams, suggesting that the process of geostrophic adjustment is important in their formation. The temporal continuity of wind profiler measurements provides the most unambiguous way of measuring this poorly understood class of gravity wave.

The ability of wind profilers to measure coincident horizontal and vertical wind components provides a way to measure momentum fluxes from gravity waves, which are

Figure 5 Example of mesospheric summer echo observed in midlatitudes by the Aberystwyth MST radar. Courtesy of the NERC MST Radar Facility. MST, Mesosphere–Stratosphere–Troposphere.

required for parameterization of the contribution of gravity waves to the momentum budget, particularly in the stratosphere and mesosphere.

Convection

Convection is particularly evident in data from boundary layer profilers, where the growth and decay of the mixed layer during daytime may be clearly observed in echo power, vertical velocity, and spectral width (e.g., Figure 3). With a typical time resolution of 15 min or more, the radars do not resolve individual thermals, but in unstable environments where deeper convection forms, the resulting plumes are clearly visible. If convection is sufficiently deep to result in precipitation, the strong particle echoes dominate the weaker clear-air scattering, as described above.

Deep convection is also clearly visible in VHF radar echoes, with similar characteristics to the UHF echoes except that particle scattering is only appreciable for very large storms. Typically, deep convection reduces the ability of a VHF profiler to measure winds because of the loss of horizontal homogeneity in the wind field.

Atmospheric Layers

The use of radar echo power to identify the boundary layer top and the tropopause has already been introduced in Section [Signal Power and Turbulence](#), but radars can be used to detect other layered structures as well. Fronts, for example, show up clearly as sloping layers (with time) of enhanced wind shear beneath a jet stream, often with maxima in echo power as well. Indeed, tropopause folds, which are upper-level fronts containing a layer of stratospheric air sandwiched between layers of tropospheric air, are particularly clearly observed – the echo power maximum in this case corresponding to the enhanced stability and negative humidity gradient at the base of the fold (eqn [4]). In the stratosphere, layers of turbulence may be detected above a jet stream or in regions of gravity wave breaking – demonstrating the sporadic and local nature of turbulent mixing in this part of the atmosphere.

Radar Networks

Individually, wind profilers can depict in great detail the dynamics of the atmosphere at one location, but do not reveal horizontal variations unless further assumptions are made, for example, about the speed of passage of a front. To address this deficiency, a network of profilers is required. Such networks have been established by meteorological agencies in a number of countries, for example, that of the National Oceanic and Atmospheric Administration (NOAA) in the United States, Japan Meteorological Agency in Japan, and the E-WINPROF network in Europe. Wind profiles are readily assimilated into numerical weather forecasts, and the continuous coverage available from wind profilers makes them particularly suitable for assimilation into mesoscale models: with grid spacing of a few kilometers the detail in these models far outstrips that of the conventional observing network. Most network radars are of the UHF type – both because of cost and because the observational requirement is most acute in the boundary

layer – but VHF radars of varying size and complexity are also included (e.g., the Aberystwyth MST radar).

In the mesosphere, networks of radars can investigate the propagation of planetary waves and tides – disturbances with horizontal scales of thousands of kilometers. MST radars are used here in conjunction with other radar types, for example, meteor radars or medium frequency radars.

Conclusions

Wind profiling radar is by now an established technology, which has moved from specialist research applications to operational observations and from single instruments to coordinated networks of radars. Profilers are manufactured commercially by a number of companies worldwide, for example, Scintec and Degreane at UHF and ATRAD and Genesis at VHF, although the most powerful systems capable of mesospheric observations remain in the research domain. The great strength of wind profilers is the reliability of the technology – operational coverage of 98% over the course of a year is possible, and measurements are not affected by the presence of cloud or degraded by precipitation. The radars can operate autonomously and the data processed and distributed in real time – an essential attribute for operational meteorology. At the same time the technique is flexible and can be tailored to specific research applications – for example, the use of frequency-domain interferometry for enhanced vertical resolution, or data recording at high time resolution for PMSE observations.

Wind measurements from profilers are well characterized at stratospheric and tropospheric altitudes, but the scattering mechanisms, especially at VHF, are still only partially understood – in particular the nature of the predominant aspect-sensitive echoes. For this reason, echo power profiles at VHF are not as well exploited as at UHF where active turbulence dominates. Spectral width, corrected for various factors like beam broadening and shear broadening, is generally accepted to provide a measure of turbulent intensity for strong turbulence, but further work is needed to establish the validity of such expressions as eqns [6] and [7]. In the mesosphere, the scattering mechanism for PMSEs is still the subject of debate, and there have been fewer opportunities to validate MST radar winds by comparison with other techniques.

Novel applications of wind profilers come when they are combined with other techniques. The most obvious is radio acoustic sounding, a combination of wind profiler and sodar, which is able to measure virtual temperature profiles in the lowest few kilometers of the atmosphere (the radar measures the speed of the sound wave, providing a direct measure of temperature). Many of the NOAA network radars, for example, have this capability. Lidar is another active remote sensing technique, which complements a wind profiler – for example, in measurements of cloud base in operational meteorology, or stratospheric temperature profiles for gravity wave studies. Airglow cameras provide an all-sky perspective on mesospheric gravity waves, and complementary use of other mesospheric radars has already been noted. Further developments of wind profiler applications are under way in profiling humidity (using microwave radiometers) and measuring cloud dynamics (in conjunction with vertically pointing cloud radars).

This article has provided an overview of the technique of wind profiling and a brief summary of the major applications. For further information, the reader is advised to consult the references provided below or up-to-date reference books on radar meteorology.

Meteor Radar

NJ Mitchell, The University of Bath, Bath, UK

Synopsis

Meteor radars detect the ionized trails left by meteors in the mesosphere and lower thermosphere. The trails are advected with the winds at the heights where they form and so can be used as tracers of atmospheric motion. Meteor radars typically measure zonal and meridional winds with time and height resolutions of about 1 h and 3 km, respectively. The radars are often simple and robust, making them ideal for extended deployment at remote sites. They are well suited to studies of background winds, tides, and planetary waves. Recent advances offer the possibility of making statistical measurements of gravity wave fluxes.

Introduction

Meteors, colloquially ‘shooting stars,’ can be among the most beautiful and striking phenomena of the naked-eye night sky. Measuring radio waves reflected from the ionized trails that meteors create has proved a powerful tool in investigations of meteors and the region of the atmosphere in which they occur. Meteor trails are carried by the winds at the height where they form, and so High-Frequency (HF) and Very-High-Frequency (VHF) radar Doppler measurements of the drift velocities of radio meteors allow determination of these winds – essentially using the meteors as tracers of atmospheric motion. Most radio meteor echoes are detected at heights between ~ 70 and 110 km. This is the upper part of the middle atmosphere and spans the upper mesosphere, the mesopause, and the lower thermosphere. These regions are otherwise notoriously difficult to investigate experimentally because they are too high for *in situ* measurements other than those made by rockets.

Meteor radars have thus played an important role in elucidating many aspects of the dynamics of this part of the atmosphere, particularly with regard to the mean winds, tides, and planetary waves that dominate the flow at these heights. Many types of radar can detect meteors, but here we will concentrate on purpose-built meteor radars used to investigate the dynamics and structure of the mesosphere and lower thermosphere. Particular attention will be given to the nature of the radio reflections from meteors and to illustrating the capabilities, strengths, and limitations of these radars for studying the dynamics of the meteor region of the atmosphere.

Meteor Radar in Context

Radio studies of meteors prior to the 1970s were mostly concerned with various aspects of meteor astronomy and with understanding the physical mechanisms responsible for the observed properties of meteor echoes. Once the basic physical mechanisms had been uncovered, it was realized that it is possible to use the drifting of radio meteors as tracers of atmospheric motion at meteor heights. Early successes included some of the first measurements of the general circulation of the mesosphere and lower thermosphere and the identification of various large amplitude tides and planetary wave modes that are major features of the dynamics of the atmosphere at these heights. Coordinated studies with

instruments at different locations allowed determination of the zonal and meridional structure of some of these winds, tides, and planetary waves.

Significant early work was often achieved even by simple radars operating without any ability to determine echo heights and so restricted to measuring winds representing a mean across the depth of the meteor region, weighted by the vertical distribution of meteor echoes (see below).

In the 1980s and early 1990s, the development of other techniques, particularly medium frequency (MF, or partial reflection) radar, mesosphere–stratosphere–troposphere (MST) radar, incoherent scatter (IS) radar, and resonance and Rayleigh backscatter lidar, to some extent overshadowed meteor radar as a tool for atmospheric studies.

In the twenty-first century, however, there has been something of a renaissance in meteor radar work. This is partly because of the development of new radio meteor techniques, and partly because sophisticated, commercially produced, purpose-built meteor radars are now available at relatively modest cost. Such systems offer accurate echo height finding and are capable of continuous operation over periods of many years with minimal maintenance, making them well suited to operation at remote sites. These factors have combined to greatly increase the number of meteor radars deployed. Presently, about 35 dedicated meteor radars operate around the world on a near-continuous basis, the great majority of which are modern commercially produced systems.

Radio Echoes from Meteors

A meteor occurs when a particle of interplanetary material, a meteoroid, enters the Earth’s atmosphere and ‘burns up.’ The majority of meteors detected by a typical meteor radar are caused by particles of less than 1 mm radius. Meteor entry speeds are in the range ~ 11 – 72 km s^{-1} and so rapid frictional heating occurs as the particle encounters the atmosphere. Once the meteoroid surface temperature reaches values of $\sim 1850 \text{ K}$, the surface ablates and significant mass loss results. The visible light emitted from the meteor arises mostly from the de-excitation of these excited meteoroid atoms lost from the particle’s surface. Inelastic collisions between these ablated atoms and the surrounding air molecules then produce an approximately cylindrical ionized trail behind the meteoroid particle.

The free electrons in this trail are able to scatter incident radio waves and so the meteor can be detected by radar systems. Although it is possible to detect a radio echo associated with the advancing ‘head’ of the meteor, atmospheric science measurements generally use the specular reflection observable in a direction perpendicular to the ionized trail axis. A full treatment of meteor physics and meteor scattering theory is quite involved and so here the theory will only be outlined briefly.

The structure of the ionized trail initially left by the meteor is a function of the entry speed, entry angle, and initial mass of the meteoroid particle. The trail’s initial radial structure consists of a core of high ionization density surrounded by less dense ionization in an outer region. The initial ionized trail radius is defined by the root mean square value of the radial position of the ablated ions after they have undergone the 10 or so collisions necessary to reach thermal equilibrium.

Atmospheric mean free path increases with height, and so the formative trail radius will be greater at greater heights. The initial trail radius also varies with meteor speed, but for a typical 40 km s^{-1} meteoroid the trail will form with an initial radius of $\sim 0.3, 0.6,$ and 1.2 m at heights of $75, 90,$ and 105 km , respectively. The trail itself will typically span some $10\text{--}15 \text{ km}$ in height. The electron line density of the trail is also a function of meteoroid mass and entry angle, but the majority of observed values are less than $\sim 10^{14} \text{ m}^{-1}$.

The amplitude of the radio echo received will rise rapidly to a maximum as the meteor moves past the specular reflection point, with most of the recorded signal being from the first Fresnel zone. The echo behavior after this maximum depends strongly on the electron line density. If the line density is below $\sim 10^{13} \text{ m}^{-1}$, then the radio wave fully enters the trail and the scattered signal that is received results from the individual contributions of all the electrons in the trail.

However, the trail radius will increase with time because of ambipolar diffusion. Within a few seconds the radius will have become sufficiently large that for typical radio wavelengths of some $\sim 5\text{--}10 \text{ m}$, destructive interference from scatter at different depths within the trail will extinguish the echo amplitude. The echo amplitude will thus decrease rapidly from the peak value. Such meteor echoes are known as underdense, and the time of decay to half peak amplitude, $t_{1/2}$, is related to the ambipolar diffusion coefficient, D , and radio wavelength, λ , by eqn [1].

$$t_{1/2} = \frac{\lambda^2 \ln 2}{16\pi^2 D^2} \quad [1]$$

Figure 1 presents the amplitude–time profile of a typical underdense echo. In this case, the echo lasts for $\sim 1 \text{ s}$ after the peak amplitude is reached before returning to the noise level again. This characteristic short-lived echo profile is very useful in distinguishing genuine meteor echoes from potentially spurious signals such as those from lightning or those produced by reflections from aircraft.

This destructive interference phenomenon also limits the greatest height at which underdense meteors can be detected using a particular radio wavelength, since at some upper height the trails will form with radii sufficiently great for destructive interference to occur instantly. This is sometimes known as the underdense echo ceiling. Here we should also note that

Figure 1 The amplitude profile of a characteristic underdense meteor echo, in this case recorded by the Advanced Meteor Orbit Radar (AMOR) in New Zealand (Jack Baggaley, private communication).

magnetic and electric fields may modify the behavior of meteor trails somewhat. For instance, magnetic fields result in anisotropic diffusion at heights above $\sim 95 \text{ km}$.

A minority of echoes will come from meteors with electron line densities greater than $\sim 10^{15} \text{ m}^{-1}$. In this case, secondary scattering between electrons becomes significant and the radio wave is reflected from the surface of the meteor trail as from a metal surface (i.e., dielectric constant <0). Such echoes are known as overdense, and do not show the rapid fall off in amplitude of the underdense echo. Overdense echoes may persist for many seconds, and the lifetime is determined by recombination processes that ultimately extinguish the meteor ionization.

Overdense echoes are less useful because the echo amplitude may fluctuate in a rather random manner as wind shears distort the trail and give rise to constructive and destructive interference from multiple specular reflection points. This makes unambiguous discrimination of the echo from noise more difficult. Such distortions may also cause a specular reflection point to move along the distorting trail, giving a spurious drift velocity. Electron line densities of $\sim 10^{14} \text{ m}^{-1}$ yield transitional behavior between the two echo types.

Typical Meteor Radars

A wide variety of radar powers, modes of operation, and antenna patterns can be used to detect meteors. Typically, a purpose-built system might be a pulse radar having the following parameters:

Operating frequency	25–60 MHz
Peak power	6–200 kW
Duty cycle	1–15%
Pulse repetition frequency	200–2000 Hz

The operating frequency must be selected to be high enough so that interference from ionospheric scatter is not significant,

but low enough so that the underdense echo ceiling does not become so low in height that it significantly reduces meteor count rates. Pulse repetition frequencies must be high enough that sufficient samples are recorded from a given underdense echo to determine its parameters before the echo amplitude decays back to the noise level. The set of parameters determined for each individual meteor echo would usually include the following: range, elevation and azimuth angles, power, echo decay time, and radial drift speed (which is measured by Doppler techniques).

Typically, the distribution of radial drift speeds is approximately Gaussian with a full width at half maximum of $\sim 55 \text{ m s}^{-1}$. An uncertainty in individual radial drift speeds of $< 2 \text{ m s}^{-1}$ might be attained for at least 50% of meteors recorded and nearly all would have uncertainties of $< 5 \text{ m s}^{-1}$.

Various antenna configurations can be used. So-called all-sky systems are now almost universally used in purpose-built meteor radars designed for atmospheric science. These systems use low-gain antennas to illuminate a large volume of the meteor region around the radar. Echo azimuth and elevation angles are usually determined by an array of receiver antennas acting as an interferometer. Horizontal wind speed and direction for a particular height range are then calculated by a least-squares fitting procedure applied to the individual radial drift measurements made over all azimuth angles. Note that these derived winds will thus be means over the horizontal extent of the radar's meteor collecting volume.

Beam systems will typically use relatively narrow beams and deduce horizontal flow speed and direction by ascribing the radial velocities measured in a particular beam to the azimuth of that beam's axis. If height information is not required, such a system needs no interferometer and can be particularly simple and inexpensive. The resulting winds are then taken to represent a mean over the meteor region weighted by the vertical distribution of meteor echoes.

Usually, this would mean considering the winds to be representative of heights of $\sim 90\text{--}95 \text{ km}$. Some radar systems designed primarily for other purposes, such as the HF Super-DARN radars, can make meteor measurements of this type.

Patrol-type radars may operate at low power and only switch to high power once a meteor is detected, or may rotate transmitted power between different beams, dwelling in one direction only once a meteor has been detected.

Finally, we should note that the specular nature of the radio reflection means that the majority of meteors falling into a radar's collecting volume will still not be recorded simply because the trail/radar geometry does not permit a perpendicular reflection, even for so-called all-sky radars. Regardless of the particular beam geometry used, the individual radial meteor drifts are used to deduce a horizontal flow in the atmosphere under the reasonable assumption that the vertical flow velocities are very small compared to the horizontal velocities on timescales comparable to the achievable time resolution (generally $\sim 1 \text{ h}$). Further, it is usually assumed that at any particular height the atmospheric flow is uniform over the entire horizontal extent of the meteor collecting volume. Vertical flows cannot be measured easily by meteor radars.

The strengths and limitations of meteor radars as tools for investigating the atmosphere are thus largely a consequence of the distribution of the recorded meteor echoes in space and time. To illustrate this, we will consider data recorded by a very typical modern all-sky radar, in this case a commercially produced SkiYmet radar located at Rothera in the Antarctic (68° N , 68° W). This particular radar operates at a frequency of 32.5 MHz , has a peak power of 6 kW , a duty cycle of 15%, and a pulse repetition frequency of 2144 Hz . It uses an array of five receiver antennas acting as an interferometer to allow determination of echo azimuth and elevation angles, which in combination with range information allow echo height determination. [Figure 2](#) shows one of the crossed-element Yagi

Figure 2 One of the receiver antennas of a typical all-sky meteor radar. In this case, the radar is at Rothera (68° N , 68° W) in the Antarctic.

receiver antennas used, a rather typical antenna for this type of radar. Note that, although radars of differing transmitted power, antenna polar diagram, radio frequency, etc. will give slight variations in these distributions, their general character is representative of nearly all purpose-built meteor radars.

We now consider the spatial distribution of meteors recorded by the radar. Figure 3 shows the distribution of the 4617 individual meteors recorded on a particular day, projected onto a horizontal plane. The meteors are distributed in a circular pattern around the radar at horizontal distances up to 300 km. Allowing for the circular gaps in the distribution (caused by the receivers being short-circuited during the transmission of successive radio pulses) the peak in the horizontal range distribution of meteors is at about 120 km. The vertical distribution of these meteor echoes is illustrated by the histogram in Figure 4. Note how the distribution is strongly peaked at a height near 90 km, and how very few meteors are recorded below 80 km or above about 100 km. These figures highlight two key differences between the data from a typical meteor radar and those from, say, MF, MST, and IS radars.

First, these other techniques generally produce measurements that are essentially volume averages, usually resulting from scatterers distributed throughout a volume defined by the intersection of the transmitted beam with the height range of interest. Because the transmitted beams are quite narrow, the measured wind fields are deduced from a volume of atmosphere perhaps only a few kilometers in horizontal extent. In contrast, meteor radar measurements arise from quite localized scatter from individual short-lived meteors, but the meteors themselves are rather randomly distributed within a much larger collecting volume in the meteor region, which may extend horizontally for several hundred kilometers around the radar. The winds derived for a particular height range will

Figure 3 The distribution of 4617 individual meteors detected by an all-sky meteor radar at Rothera (68° N, 68° W) in the Antarctic, recorded on 28 August 2008. The meteor locations have been projected onto a horizontal plane with the radar at the central position. The clear rings in the distribution mark where the receiver antennas are short-circuited during the transmission of successive transmitter pulses.

Figure 4 The vertical distribution of the meteors presented in Figure 3.

therefore represent the bulk motion of a slab of atmosphere that is only a few kilometers deep but that has a horizontal extent of several hundred kilometers. This means that a meteor radar cannot easily resolve structure on horizontal scales less than a few hundred kilometers.

Second, the vertical depth of atmosphere from which sufficient meteors are recorded for reliable calculation of winds is comparatively small. In the example presented here, winds can be effectively calculated only for heights between about 80 and 98 km, because above and below these heights there are too few meteors for reliable wind estimates to be made. Note that meteor radars using a beam, rather than all-sky, configuration will still share these properties, since to ensure adequate meteor count rates the beams must be quite broad.

Finally, there is also a distinct diurnal cycle in the count rate of meteor echoes. This is largely an astronomical phenomenon resulting from the Earth's orbital motion and rotation, which causes it to sweep up meteors on its leading hemisphere, whereas a meteor must overtake the Earth in order to hit the planet's trailing hemisphere. The effect is strongest at lower latitudes and for beam systems. The net result is that meteor count rates will generally be lowest in the second part of the day, although complex geometrical and instrumental considerations will greatly influence the magnitude of the diurnal variation recorded by any particular radar.

As an example, Figure 5 presents normalized hourly mean count rates for three meteor radars. The first is an all-sky radar operated at Esrange (68° N), the second is a twin beam radar operated in the United Kingdom (52° N); and the third is an all-sky radar operated on Ascension Island (8° S) in the equatorial Atlantic. It can be seen that even in the favorable all-sky, high-latitude case the ratio of maximum to minimum hourly meteor count rates is about 2:1, and for the midlatitude beam

Figure 5 The diurnal cycle in hourly normalized meteor count rate for three meteor radars: the ESRANGE all-sky radar at 68° N (solid); a two-beam radar at 52° N in the United Kingdom (dashed); and a second all-sky radar at 8° S on Ascension Island (dotted).

system and the equatorial all-sky system it is about 10:1. This effect means that care must be taken in deriving winds for the low-count-rate part of the day (since there are simply fewer meteors to work with).

These distributions of meteors in space and time determine the resolution of the resulting wind measurements. They will generally have reasonable height and time resolutions of ~ 3 km and ~ 1 h, respectively, but poor horizontal resolution (although, as noted, not all radars actually determine echo heights). This rather unexciting sounding aspect of the data is counterbalanced by the almost unequalled ability of meteor radars to record continuous high-quality data sets over many years, without reliance on particular geomagnetic conditions, weather, or time of day.

All these factors influence the particular aspects of mesosphere/lower thermosphere dynamics that can be studied easily using meteor radar winds. Generally, the mean flow, tides, and planetary waves all have horizontal scales so large that the poor horizontal resolution of the radars is irrelevant. The vertical scale sizes and wavelengths of these phenomena are also significantly larger than the normal height resolution of a few

kilometers, and so meteor radars can make detailed studies of the vertical structure of these features across the meteor region. Meteor radars are thus well suited to the study of mean winds, tides, and planetary waves and have made very significant contributions in this area. This is particularly so because the radar hardware is often quite simple and well suited to prolonged operation over periods of years at remote sites with only limited maintenance.

An example of the mesospheric winds measured by a meteor radar is presented in Figure 6. The figure shows hourly mean zonal winds recorded by the all-sky meteor radar at Bear Lake Observatory (42° N, 112° W) in Utah, USA. The figure reveals a motion field dominated, in this case, by the oscillations of the 12-h tide, which increase in amplitude with height and display a high degree of short-term variability.

Unlike the large horizontal scales associated with winds, tides, and planetary waves, the horizontal wavelengths of gravity waves can often be comparable to or smaller than the horizontal extent of the meteor collecting volume. Self-cancellation thus occurs between different parts of the wave phase measured across the meteor collecting volume. In effect, the individual gravity waves cannot be resolved. Because of this, meteor radars have not usually been used in studies of gravity waves.

Recently, however, analysis methods have been developed to address this problem. These methods use the radial velocities measured for individual meteor echoes within the meteor collecting volume to determine statistical properties of the total gravity wave field in the meteor collecting volume, without having to resolve individual gravity waves. In particular, estimates can be made of the degree of gravity wave activity (measured by the variance of the perturbation winds), the anisotropy of the wave field propagation azimuths and the vertical fluxes of horizontal momentum. The latter estimates require measurement of the vertical perturbation velocities induced by gravity waves. Because of this, radars optimized for gravity wave measurements will sometimes use antenna configurations designed to enable the detection of meteors at higher elevation angles, such that the radial velocity will then provide information on vertical winds. Measuring momentum fluxes at different heights then allows an estimation of the divergence of the momentum flux and thus the associated acceleration of the mean flow, which is a parameter of great interest in understanding the large-scale dynamics of the mesosphere.

Figure 6 The zonal winds recorded in September 2011 by a meteor radar at Bear Lake Observatory (42° N, 112° W) in Utah, USA. The data have a time resolution of 1 h and a height resolution of about 3 km. The winds are dominated by the 12-h tide, which reaches large amplitudes in autumn at middle latitudes.

Other Measurements Using Meteor Radars

Meteor radars have also been used extensively for studies of the astronomical aspects of meteors, including measuring meteor fluxes, size distributions, entry speeds, and orbits. Other work has expanded the capabilities of the technique for atmospheric science measurements. In particular, various methods have been used to relate the ambipolar diffusion coefficient (measured from echo decay times) either to temperature–pressure-related quantities such as T^2/P or to wave-induced fractional perturbations of temperature or pressure. The poor quality of available absolute pressure estimates for the upper mesosphere prevents these methods from being used to infer absolute temperature values.

However, a recent extension of these methods has seen the application of a scale height analysis of ambipolar diffusion coefficients to determine absolute atmospheric temperature at the height of peak meteor counts without any reliance on knowledge of pressure. This capability is potentially very useful because ground-based measurements of atmospheric

temperature at meteor heights are otherwise extremely difficult to make on an extended basis.

Glossary

A Echo amplitude.

ADC Analog-to-digital converter.

ATSR Alternate transmit simultaneous receive.

B_6 Receiver bandwidth.

D_e Equivalent diameter of a raindrop.

E_h, E_v Electric field components polarized horizontally, vertically.

c Speed of light.

$E[x]$ Mean or expected value of x .

f_t Transmitted frequency.

f_d Doppler frequency.

$I(r, t)$ Real part of $V(r, t)$.

j $\sqrt{-1}$, imaginary unit.

K_w The complex dielectric factor for water.

m Integer index.

mT_s Sample time.

$n(\vec{r})$ Density of scatterers.

P_{av} Average power transmitted.

P_t Peak power transmitted.

PAR Phased array radar.

PPAR Polarimetric phased array radar.

NWRT National Weather Radar Testbed.

$Q(r, t)$ Imaginary part of $V(r, t)$.

r Range.

s_{hv} Complex backscattering matrix element.

STALO Stabilized local oscillator.

STSR Simultaneous transmit simultaneous receive.

t Time.

T_s Pulse repetition time (sampling time).

$U(x)$ $U = 1$ if $0 < x < \tau_v$; otherwise $U = 0$.

$V(r, t)$ Echo voltage.

V_6 Resolution volume.

v_r Radial velocity.

WSR Weather surveillance radar.

Z_h, Z_v The reflectivity factor measured with H, V polarized waves.

Z_{DR} Differential reflectivity factor.

ϕ_0 Beam azimuth.

ϕ Beam azimuth relative to north.

θ_e Beam elevation angle.

θ_0 Zenith angle.

θ_1 One-way beamwidth at the half-power level.

λ Wavelength.

σ_v Spectrum width.

σ_τ Correlation-time along mT_s .

τ_c Correlation-time along τ_s .

τ_s Range-time.

τ_t Transmitted pulse width.

ψ Sum of phase shifts within the radar and the scatterer.

ψ_e Echo phase.

Synopsis

The theory of, and sample results from, Polarimetric Doppler Weather Radar are presented so readers can have an explanation of the foundations upon which weather radars are used by nations to provide to their citizens timely warnings of weather hazards, to make quantitative measurements of depths of precipitation fall, and to classify precipitation types.

Introduction

The term ‘Doppler’ is in honor of the Austrian physicist, Christian Johann Doppler, who first explained the principle of the ‘Doppler effect’ in 1842. The Doppler effect is the increase or decrease in the pitch or frequency of sound waves when a source of waves is moving toward or away from the listener. This is quite evident to an observer who is listening to the blare of an automobile horn as it passes by. The observer hears first a relatively high frequency wave and then a marked drop in frequency.

Electromagnetic waves (e.g., light and radio waves) emitted from galaxies also have Doppler shifts. Spectral lines of emitted radiation are Doppler shifted to lower frequencies because most galaxies are moving away in our expanding universe; blue spectral lines are shifted to lower frequency red lines, the so-called red shift.

Unlike sound waves, which have vibrations in the direction of propagation, electromagnetic waves have vibrations in a plane transverse to the direction of propagation. Through careful design of the radar, the direction of the electric field in

the plane of oscillation can be controlled thereby creating a particular *polarization*. The polarization of the electromagnetic waves has a profound effect on their interaction with scatterers (e.g., hydrometeors, insects, refractive index perturbations, etc.) in the atmosphere.

Doppler weather radars owe their acceptance by the weather services around the world to the fact that radio waves having wavelengths on the order of centimeters can penetrate extensive fields of precipitation (e.g., hurricanes) to map and reveal, like an X-ray photograph, the internal structure and motion of weather systems. Optical and infrared waves do not penetrate very far into clouds and precipitation.

The next section shows how radar uses the Doppler effect to measure the radial velocity of scatterers in the earth’s atmosphere, and how it measures the polarimetric properties of radiation backscattered from these scatterers to improve estimates of rainfall and to distinguish various types of hydrometeors (e.g., rain, snow, hail, etc.). In Section [Fundamentals of Polarimetric Doppler Radar](#), the basic theory of weather radar is provided for backscatter from a single hydrometeor. The theory is then extended to a volume of hydrometeors in Section [Volume Scattering](#), and samples of polarimetric and Doppler data are shown to emphasize the usefulness of these measurements to observe weather phenomena. Finally, the authors’ perspective on the future of weather radar is provided.

The Doppler Shift and Polarimetric Properties of Scatterers

Scatterers in the atmosphere produce measurable Doppler shifts if the scatterers are illuminated with narrow band radiation (e.g., a radio wave transmitted at a single frequency, f_i). Radio waves incident on a scatterer force electromagnetic vibrations in the scatterer. If the scatterer is at constant range r from the radar, vibrations are at f_i . If the scatterer moves toward the radar, the internal vibrations will be faster because the wave’s apparent propagation speed relative to the scatter is faster and thus the approaching scatterer experiences more rapid fluctuations of the incident waves. Thus the backscattered radiation (i.e., echoes) received by the radar will have a frequency higher than f_i .

Doppler weather radars typically transmit microwave radiation in bursts of short duration, τ_t (e.g., 10^{-6} s or 1 μ s). These radars are called pulsed Doppler radars to distinguish them from those that emit continuous waves such as radars used by police to detect the speed of automobiles. Pulsed Doppler radars can measure both range r and radial velocity v_r of scatterers.

The US National Weather Service (NWS) network of Doppler weather radars emits 1.57 μ s duration pulses of 10-cm wavelength $\lambda = c/f_t$ radiation (i.e., similar to the λ used in microwave ovens; c is the speed of light) to map r and v_r of hydrometeors. These radars are called WSR-88Ds, where WSR is an acronym of Weather Surveillance Radar. The number 88 denotes the year (1988) a contract was issued for a limited production and testing; the first unit for routine operation was installed in the late 1992 and the last radar of a network of about 160 radars was installed in 1997; the letter *D* represents its Doppler capability; polarimetric upgrades were completed in 2013.

The measurement of the Doppler shift in a single back-scattered pulse (i.e., an echo from an object, small compared to $c\tau_t$) of microwaves is not practical. Instead, the change of the echo’s phase angle from one transmitted pulse to the next is measured. Phase angle is proportional to the scatterer’s range and equals twice the number of wavelengths, and portions thereof, between the radar and the scatterer. Phase angle measures quite precisely (i.e., to fractions of a wavelength) the distance to the scatterer, but there is ambiguity because the phase can be only determined within a wavelength. Nevertheless, the change of the echo phase, from pulse to pulse, is used to measure v_r , the time rate of change of range to the scatterer.

If all hydrometeors were spherical, polarization would not play a major role in the design of weather radar. In stark contrast, hydrometeors can be found in a variety of shapes, sizes, orientations, and size distributions. Simple visual observations of snow, for example, exemplify the vast array of possibilities. Even raindrops, which are often thought to be spherical, exhibit deformation due to the drag force. This effect becomes gradually more important with increasing drop size, as illustrated in [Figure 1](#). Note that liquid cloud droplets with diameters on the order of microns are nearly spherical and thus equally backscatter linearly polarized waves of any orientation – e.g., horizontal *H* or vertical *V* polarization. The equivalent diameter D_e is the diameter of a spherical drop having the same volume as the deformed drops shown in the figure. Also shown in the figure is the *differential reflectivity*, Z_{DR} , a measure of the ratio of backscatter from *H* and *V* polarized waves.

Nonhydrometeorological scatterers found in the atmosphere (e.g., insects, birds, aircraft, etc.) typically are nonspherical. For these reasons, polarimetric signatures of scatterers are important for weather radar design and can be used for more precise characterization of their properties, leading to accurate rainfall estimates and the capability of distinguishing rain from snow, hail, insects, etc.

Polarimetric weather radar produces electromagnetic oscillations in a plane – the plane of polarization – orthogonal to the direction of wave propagation. In this plane, the electric

Figure 1 Shapes of raindrops falling in still air and experiencing drag force deformation. D_e is the equivalent volume diameter of a spherical drop. Z_{DR} (dB) is the differential reflectivity in decibels for each drop back-scattering 10-cm-wavelength radiation. This figure is adapted from one in Pruppacher, H.R., Beard, K.V., 1970. A wind tunnel investigation of the internal circulations and shape of water drops falling at terminal velocity in air. Quarterly Journal of the Royal Meteorological Society 96, 247–256.

field vector can be decomposed into two components having orthogonal directions, H and V , the horizontally and vertically polarized components. For H polarization, the vibrations are parallel with the ground, but for the V polarizations the vibrations lie in a vertical plane as illustrated in Figure 2. Due to the nonspherical shape of most hydrometeors, the backscattered signals from each of these linear polarizations will be different; quantification of these differences is the foundation of polarimetric radar.

H and V polarization is often implemented using the simultaneous transmit simultaneous receive (STSR) mode, as illustrated in Figure 2. As the name implies, electromagnetic waves with both H and V polarizations are transmitted simultaneously. In the STSR mode, the backscattered radiation from the scatterers is also received simultaneously in H and V receivers. Another mode alternates, from pulse to pulse, the H and V transmissions, but has simultaneous H and V reception (alternate transmit simultaneous receive (ATSR)). The major advantage of the ATSR configuration is its capability to measure *cross-polar* signals, where backscatter from a horizontally polarized transmitted pulse is received with vertical polarization or vice versa. Such cross-polar measurements do contain meteorological information but are extremely weak compared to the *copolar* signals (e.g., H polarized echoes are received when H polarized pulses are transmitted). Implementation challenges of the ATSR mode with high-powered transmitters contributed to the decision by the NWS to use the STSR mode for the WSR-88D network (Doviak et al., 2000).

Consider a single stationary hydrometeor at range r . The effects on the polarimetric signature can be divided into two components: *propagation effects* and *backscattering effects*. If no precipitation exists between the radar and the hydrometeor, propagation effects can be ignored and any polarimetric signature would be due solely to backscattering effects. For clarity, we will ignore propagation effects. In this case, the backscattered electric field is described by the following matrix equation (Doviak and Zrnić, 2006, eqn [8.39])

Figure 2 Electromagnetic waves propagating with H and V polarizations aligned in time (i.e., *in phase*). When two waves with H and V polarizations are simultaneously transmitted in phase, the resulting composite electromagnetic field oscillates along a 45° angle – called *slant linear 45°* – in the plane of polarization.

$$\begin{bmatrix} E_h \\ E_v \end{bmatrix}^b = \begin{bmatrix} s_{hh} & s_{hv} \\ s_{vh} & s_{vv} \end{bmatrix} \begin{bmatrix} E_h \\ E_v \end{bmatrix}^i \frac{\exp(-jkr)}{r} \quad [1]$$

where E_h and E_v are the electric field components in the h and v directions, the superscripts i and b correspond to the incident and backscattered fields, respectively, $j = \sqrt{-1}$, and s_{hv} is the complex backscattering cross section when the incident wave is vertically polarized and the horizontal component of the backscattered electric field is measured. The other elements of the backscattering matrix follow accordingly. s_{hv} is called complex because it has magnitude – proportional to the size, shape, and orientation of the hydrometeor – and phase. The exponent of the exponential factor in the equation is also a phase term. The magnitudes and phases fluctuate in time because the hydrometeor's size, shape, and orientation change due to turbulence and collisions. By independently transmitting and receiving horizontal and vertical polarizations (e.g., ATSR mode), it is possible to measure all the elements of the backscattering matrix, although the cross-polar terms (s_{hv} and s_{vh}) are one to two orders of magnitude weaker than the copolar terms (s_{hh} and s_{vv}). In contrast, the STSR mode allows relatively easy measurement of only the *copolar* terms (s_{hh} and s_{vv}) but sophisticated coding schemes (Chandrasekar and Bharadwaj, 2009) are required to estimate s_{hv} .

Fundamentals of Polarimetric Doppler Radar

The fundamentals of polarimetric Doppler radar can be more easily explained by discussing a simplified block diagram of polarimetric homodyne radar (Figure 3). Weather radar has an oscillator called the STALO (stabilized local oscillator), which generates a very pure continuous microwave (i.e., a spectral line) at a frequency, f_c . This continuous wave is converted to a sequence of microwave pulses by the modulator. Frequency f_c is called the carrier frequency because it carries the modulation pulse. The transmitted microwave pulses, of time duration τ_t and spaced T_s (≈ 1 ms) are intensified by a high power amplifier (e.g., a klystron) to produce a large peak pulse power, P_t , often close to 1 MW. The average power $P_{av} = (\tau_t/T_s)P_t$, however, is typically a kilowatt or less, about that used in microwave ovens. The transmitted pulse of vertically polarized microwaves of spatial length $c\tau_t$ is in a beam, formed by the parabolic reflector antenna, directed at azimuth and elevation angles, $\phi = 90^\circ - \phi_0$ and $\theta_e = \frac{\pi}{2} - \theta_0$, respectively (radar meteorologists measure azimuth, ϕ clockwise from north). Weather radar beams typically have a circular half-power angular width $\theta_1 \approx 1^\circ$. It should be recognized that the reflector antenna, which determines the overall quality of the polarimetric signals, is the key component of the radar system. A feed placed at the focal point of the parabolic reflector emits the H and V electromagnetic energy onto the reflector.

It is difficult to make direct measurements of the H , V microwave echoes, so most receivers shift f_c either to zero – as done by a homodyne receiver – so that weather echoes can be sampled and digitized by analog-to-digital converter (ADC) electronics of the digital receiver (Figure 3) or, more commonly, to an intermediate frequency where the ADC can also be applied. The digitized data are processed by computers and results are displayed and recorded.

Figure 3 Block diagram for a single V channel – waves polarized in a vertical plane are transmitted – of homodyne polarimetric Doppler radar. For STSR mode, the klystron-amplified pulse would be sent to H (not shown here) and V channels of transmit/receive (T/R) switches and then to the dual-polarimetric antenna. The H and V receive channels (i.e., synchronous detectors, etc.) would have separate electronics to receive H , V weather echoes independently.

With advances in digital technology, modern receivers that digitize the signals at the shifted intermediate frequency and translate these signals to baseband (i.e., $f_i = 0$) are becoming ubiquitous. These so-called *digital receivers*, or *software-defined receivers*, have several advantages including a perfect quadrature relation between the in-phase and quadrature signals, and a flexible design. Since the receiver characteristics are controlled in software, updates can easily be incorporated as advances in signal processing become operational.

In a homodyne receiver, the echo of pulsed microwaves is directly passed to a synchronous detector (Figure 3) and mixed (multiplied) with signals from the STALO. A synchronous detector is required to resolve both the echo's magnitude and sign of its phase angle or Doppler shift. The two STALO signals are sinusoid and cosinusoid producing the *in-phase* $I(t)$ and *quadrature* $Q(t)$ signals, respectively.

To explain the pulse-to-pulse shift in echo phase and its relation to v_r , two cases are examined for the ATSR mode: a simple case of a stationary scatterer at r , and a more complex case when the scatterer is allowed to move. In the simple case, the copolar echo voltage (e.g., V_{hh}) at the receiver's input is essentially a scaled replica of the transmitted pulse and is given by

$$V_{hh}(r, t) = A s_{hh} \exp \left\{ j \left[2\pi f_t \left(t - \frac{2r}{c} \right) + \psi \right] \right\} U \left(t - \frac{2r}{c} \right) \quad [2a]$$

$$= A s_{hh} \left[\cos \left(2\pi f_t t - \frac{4\pi r}{\lambda} + \psi \right) + j \sin \left(2\pi f_t t - \frac{4\pi r}{\lambda} + \psi \right) \right] U \left(t - \frac{2r}{c} \right) \quad [2b]$$

The cosine and sine terms are the real and imaginary components of $V_{hh}(r, t)$ oscillating at the rate f_t . A is the echo amplitude, s_{hh} is the copolar backscattering matrix element for

HH polarization, $2\pi f_t \left(t - \frac{2r}{c} \right) + \psi$ is the microwave echo phase, t is the time the echo is received after the emission of the transmitted pulse, and ψ is the sum of phase shifts within the radar and the scatterer. The pulse function $U \left(t - \frac{2r}{c} \right)$ is unity when its argument $t - \frac{2r}{c}$ is between 0 and τ_t , and is zero otherwise. Equation [2a] is an exponential form and a compact way of expressing the microwave echo.

As just discussed, it is difficult to process the echo voltage at the transmitted microwave frequency, f_t so the microwave echo is downconverted to baseband (i.e., zero carrier frequency) using the synchronous detector (or digital receiver). An expression for this baseband signal can be obtained from eqn [2b] by setting $f_i = 0$. Thus, the echo voltage at the receiver's output (HH polarization, in this case) is

$$V_{hh}(r, t) = I_{hh}(r, t) + jQ_{hh}(r, t), \quad [3a]$$

where

$$I_{hh}(r, t) = A s_{hh} \cos \psi_e U \left(t - \frac{2r}{c} \right), \quad [3b]$$

$$Q_{hh}(r, t) = A s_{hh} \sin \psi_e U \left(t - \frac{2r}{c} \right), \quad [3c]$$

are the in-phase and quadrature components, and the echo phase is defined as

$$\psi_e = -\frac{4\pi r}{\lambda} + \psi \quad [4]$$

For simplicity, henceforth the polarimetric notation subscript on the in-phase and quadrature signals is dropped and will be used only where necessary for clarity.

Sampling in Range and Time

As shown in eqn [3], the echo voltage is a function of both range r and time t . Because pulses are transmitted every T_s ,

echoes from a stationary scatterer will periodically appear at $t = \frac{2r}{c} + mT_s$, where $m = 1, 2, 3, \dots$ defines each echo pulse. Because the scatterer's range is not known, a search for echoes is made by circuits that sample, at rates typically $> \tau_s^{-1}$, for echoes and the sampling process is reset every T_s . The T_s interval is defined as *range-time* τ_s ($0 \leq \tau_s \leq T_s$) because the location of the echo within T_s defines the range r to the scatterer. If the scatterer moves, not only will the echo pulse change its location along τ_s , but ψ_e will also change according to eqn [4]. Both echo position along τ_s and ψ_e can in principle be used to measure the change in scatterer location, and thus indirectly its radial velocity. However, ψ_e change is a more accurate measure of changes in scatterer location. For example, a change δr of r by $\lambda/4$ (e.g., 2.5 cm for the WSR-88D) causes ψ_e to change by 180° , a large angular change, whereas the change $\delta\tau_s$ along $\tau_s = 2r/c$ is $\delta\tau_s = 2\delta r/c$ (i.e., 1.67×10^{-10} s), a tiny fraction of τ_s . Thus, scatterer motion is measured by changes in ψ_e . As a consequence, the pulsed Doppler radar is an amplitude and phase sampling system (i.e., samples of A_{shh} and ψ_e at τ_s are obtained at T_s intervals). Range-time τ_s determines the range to the scatterer, and changes in ψ_e for echoes sampled at τ_s are measured from pulse to pulse along *sample-time*, mT_s . Because of this sampling process, the sampled echo voltage is written in the following form

$$V(\tau_s, mT_s) = I(\tau_s, mT_s) + jQ(\tau_s, mT_s). \quad [5]$$

This sampled echo voltage can be represented as a vector on the *Argand diagram* (e.g., Figure 4b). The carrier-shifted vector has the amplitude $|V(\tau_s, mT_s)|$ and echo phase ψ_e (positive when measured counter clockwise (ccw) from the $I(\tau_s, mT_s)$ axis).

Echo Phase Shift

Equation [4] shows ψ_e changes with time as the scatterer's r changes at a rate corresponding to its v_r . This time rate of change of ψ_e is

$$\frac{d\psi_e}{dt} = -\frac{4\pi}{\lambda} \frac{dr}{dt} = -\frac{4\pi}{\lambda} v_r = 2\pi f_d. \quad [6a]$$

where,

$$f_d = -\frac{2v_r}{\lambda} \quad [6b]$$

is the Doppler frequency f_d . Although it is possible to calculate a radial velocity for each copolar signal, v_r is the same for each polarization.

As an example, the $I(\tau_s, mT_s)$ and $Q(\tau_s, mT_s)$ components from a 10-cm-wavelength weather radar illuminating both stationary and moving scatterers are shown in Figure 4(a) as a function of τ_s for five successive transmitted pulses spaced $T_s = 768 \times 10^{-6}$ s. The echoes from the moving scatterer clearly exhibit a systematic change caused by v_r . Amplitudes of $I(\tau_s, mT_s)$ and $Q(\tau_s, mT_s)$ can change from a positive maximum to a negative maximum if the scatterer moves $\lambda/4$ in T_s . As shown earlier, under this same condition, the echo's range time τ_s changes less than 2×10^{-10} s, a shift too small to be detected in Figure 4(a).

Let us now calculate f_d and v_r from the $I(\tau_s, mT_s)$ and $Q(\tau_s, mT_s)$ changes seen in Figure 4 for the moving scatterer.

Figure 4 (a) In-phase and quadrature signals as a function of range time τ_s for five successive T_s intervals superimposed to show the echoes' relative change for stationary and moving scatterers. (b) An Argand diagram of the five echo samples in (a) for the moving scatterer.

This scatterer's five samples are sketched on the Argand diagram in Figure 4b. We see that the echo vector samples rotate ccw about the origin, and by convention this corresponds to a positive Doppler shift. Because the echo phase change $\Delta\psi_e$ between pulses 1 and 2 is approximately 60° during T_s ,

$$f_d(\text{Hz}) = 60^\circ \times \frac{1 \text{ cycle}}{360^\circ} \times \frac{1}{T_s}$$

computes to be about +217 Hz. Using eqn [6b], v_r computes to be about -10.9 m s^{-1} .

It should be mentioned that pulsed Doppler radar inherently limits both the range and velocities that can be measured unambiguously. If the radar transmits a uniform periodic sequence of pulses, which is normally the case, it is not possible to determine which transmitted pulse produced which echo. Furthermore, the periodic transmitted pulse sequence also introduces velocity ambiguities. These problems are well illustrated in a like article in the first edition of this Encyclopedia. There are several techniques to mitigate these ambiguities and the reader is referred to them for further reading (e.g., Bharadwaj and Chandrasekar, 2007; Doviak and Zrnić, 2006; Cho, 2005; Sachidananda and Zrnić, 2003; Torres et al., 2004).

Volume Scattering

Up to this point, we have discussed scattering from a single scatterer – both stationary and moving. This theory is fundamentally the same as what underpins radar used to remotely detect aircraft, ships, missiles, planets, etc. Whereas most radars are designed to detect and characterize a countable number of discrete objects (i.e., aircraft, automobile, etc.), weather radars need to characterize a countless number of hydrometeors distributed over vast volumes of the atmosphere. The echo power from each hydrometeor is very weak – a 1 mm raindrop at $r = 100$ km returns a power less than 10^{-22} W. Although each scatterer's echo is weak and usually not detectable, the sum of echo powers from an extremely large number of hydrometeors can return a strong continuum of echoes as the transmitted pulse propagates through the field of hydrometeors.

Polarimetric Doppler Weather Radars are used to estimate and map the hydrometeors' fields of reflectivity factor (proportional to the number density and size of the hydrometeors), reflectivity-weighted mean radial velocity, and polarimetric quantities. From these fields, radar meteorologists derive estimates of the fall rate and accumulation of precipitation, classify types of scatterers, and resolve storm hazards.

Other types of atmospheric radars such as wind profilers are designed to measure scatter from refractive index perturbations – caused by minute temperature and humidity variations – to measure winds in the lower atmosphere. Echoes from refractive index perturbations are called Bragg scatter (Doviak and Zrnić, 2006, Chapter 11). Mesosphere, stratosphere, and troposphere radars use large antennas (e.g., 100×100 m²), long wavelengths (i.e., $\gg 1$ m), and high average power (e.g., few tens of kilowatts) to detect Bragg scatter from the weak refractive index perturbations in the upper atmosphere (Fukao and Hamazu, 2013). Polarimetric Doppler Weather Radar can also detect Bragg scatter, but observations are limited to the troposphere, and conditions of strong refractive index perturbations.

After a delay – the time for the transmitted pulse to propagate to the near boundary of the volume of hydrometeors plus time for the first echoes to arrive at the radar – echoes are continuously received (Figure 5) during a time interval equal to twice the time it takes the microwave pulse to propagate across the volume of hydrometeors. Because one cannot resolve the echo from each scatterer, the radar's digital processors use ADCs to sample – at uniformly spaced T_s

Figure 5 Idealized traces for $I(\tau_s, mT_s)$ of weather echoes from a distribution of scatterers. The traces represent $I(\tau_s, mT_s)$ for the m th T_s interval; dashed traces connect samples (i.e., the vertical line segments) at each τ_s .

intervals – I and Q weather echo amplitudes and to convert these to numbers.

Definition of the Resolution Volume

For each sample in range time ($\tau_s = \tau_{s1}, \tau_{s2}, \tau_{s3}, \dots$), there is a resolution volume V_6 , at range $c\tau_s/2$, which is enclosed by the surface on which the angular and range weighting functions (determined by θ_1 , τ_v , and the receiver's bandwidth B_6) are $1/4$ their peak value (i.e., 6 dB below the peak); the surface has an angular width θ_1 , and, for receiver bandwidth $B_6 > \tau_v^{-1}$, a range width about equal to $c\tau_v/2$. The scatterers within V_6 are those that significantly contribute to the sampled voltage at delay τ_s (Figure 5); those outside V_6 usually make significantly smaller contributions.

The Echo Voltage

The echo voltage sample $V_{hh}(\tau_s, mT_s)$ from a volume of scatterers is the summation of the echo voltage from each scatterer. Thus it can be shown the baseband echo is

$$V_{hh}(\tau_s, mT_s) = \sum_n A^{(n)} s_{hh}^{(n)} \exp \left\{ j \left[-\frac{4\pi r^{(n)}}{\lambda} - \frac{4\pi v_r^{(n)}}{\lambda} mT_s + \psi \right] \right\} \quad [7]$$

where the superscript (n) denotes the n th scatterer at an initial range $r^{(n)}$. ADCs obtain digital samples of echoes from several hundred volumes along the beam. Examples of $I(\tau_s, mT_s)$ and $Q(\tau_s, mT_s)$ time series for echoes from scatterers in two independent V_6 s are shown as a function of index m in Figure 6. One V_6 returns echoes from quasi-stationary scatterers (e.g., a cell tower, trees, etc.); these echoes (called ground clutter because, for weather radar applications, it is unwanted and clutters signals from weather) produce slowly varying voltages. The second V_6 contains hydrometeors having radial velocities causing rapid variations of the echo voltage.

Spectral Analysis of the Echo Voltage

Temporal variations of the echo voltage in sample time mT_s hold important Doppler information about the scatterers within the resolution volume. For each range time, τ_s , echo voltage samples from M transmitted pulses and for each polarization are compiled over the *dwell time* (MT_s , the time to transmit all M pulses used in the analysis) chosen to investigate these variations. This so-called *spectral analysis* is usually accomplished using the discrete Fourier transform of the echo voltage. The main product of the Fourier transform is the power spectral density – also called the *Doppler spectrum* in the weather radar community. The Doppler spectrum provides the reflectivity-weighted distribution of radial velocities of scatterers mostly within the resolution volume. Examples of Doppler spectra are provided in Figure 6 corresponding to the series of M echo voltage samples from two V_6 s. Doppler spectra can be obtained for both H and V polarization, providing the possibility of velocity-dependent polarimetric characterization.

For the ground clutter case shown in Figure 6, the Doppler spectrum shows a prominent peak at zero Doppler velocity

Figure 6 OU-PRIME weather radar showing idealized H and V waves propagating along the beam and two V_6 s (i.e., quasi-cylindrical resolution volumes), and time series traces $I(\tau_s, mT_s)$ and $Q(\tau_s, mT_s)$ from the two V_6 s, one in a region of a ground scatterer – a tower or trees that can sway causing I and Q to change slowly with mT_s – and the other in precipitation having moving scatterers. Each trace is a sequence of echo samples (dots) spaced mT_s ; the green trace is I and the blue trace is Q . Also shown are the Doppler spectra of echo samples from the two V_6 s.

because ground objects are mostly stationary. For weather, the peak of the Doppler spectrum estimates the heaviest weighted mean radial velocity of hydrometeors. More interestingly, the shape of the spectrum holds a wealth of information about inhomogeneities within the resolution volume, such as wind shear, multiple hydrometeor types, etc. This information can be quite useful when studying phenomena such as tornadoes, squall lines, microbursts, or any weather events with a high degree of structure.

Spectral Moments and Polarimetric Products

Neither echo voltage nor Doppler spectra are typically recorded or displayed in real time; rather, digitized samples from both H and V polarizations (i.e., $V_{hh}(\tau_s, mT_s)$ and $V_{vv}(\tau_s, mT_s)$) are collected over the desired dwell time and sent to the radar's signal processor which extracts estimates of spectral moments and polarimetric parameters. Due to the typically uniform distribution of reflectivity, turbulence, and mean wind shear within V_6 , and the Gaussian shape of the beam's illumination, the Doppler spectrum often has a Gaussian shape. In this case, only three parameters completely describe the spectrum – the zeroth, first, and second moments. The zeroth moment is the area under the Doppler spectrum and is proportional to the backscattered power for each polarized wave from a particular V_6 . The first moment (i.e., the mean radial velocity $E[v_r]$) is the integral of the product of the Doppler velocities multiplied by the power spectrum normalized by the total spectral power, essentially providing the 'center of mass' of the Doppler

spectrum. The square root of the second moment of the Doppler spectrum is the spectrum width, σ_v , which is proportional to the spread of v_r within V_6 ; thus, it is a measure of turbulence and mean wind shear. It should be noted that separate moment estimates are obtained for both polarizations. Although the zeroth moments can differ significantly, as will be described below, the radial velocity and spectrum width do not have significant difference for H and V polarized waves.

Through careful calibration, the copolar backscattering matrix elements (s_{hh} and s_{vv}) can be derived from the complex echo signals with H and V polarizations. In turn, s_{hh} and s_{vv} are used to calculate important polarimetric products. The zeroth moment is used to calculate the H and V reflectivity factors (Doviak and Zmíć, 2006, section 8.5.2.2),

$$Z_h = \left(\frac{4\lambda^4}{\pi^4 |K_w|^2} \right) n(\vec{r}) \langle |s_{hh}|^2 \rangle \quad [8a]$$

$$Z_v = \left(\frac{4\lambda^4}{\pi^4 |K_w|^2} \right) n(\vec{r}) \langle |s_{vv}|^2 \rangle \quad [8b]$$

where $n(\vec{r})$ is the density of scatterers, and K_w is the complex dielectric factor for water. The angle brackets in eqn [8] indicate averaging over the ensemble of drop shapes, sizes, and canting angles (alternatively averaging over mT_s); for spherical hydrometeors $\langle |s_{hh}|^2 \rangle = \langle |s_{vv}|^2 \rangle$. For larger drops, ice crystals, hail stones, etc., these polarimetric parameters can be quite different providing information about the shape (e.g., Figure 1) of the hydrometeors. To quantify this

difference, the logarithm of the ratio of Z_h and Z_v is taken to produce

$$Z_{DR} \equiv 10 \log_{10} \left(\frac{Z_h}{Z_v} \right) = 10 \log_{10} \left(\frac{\langle |s_{hh}|^2 \rangle}{\langle |s_{vv}|^2 \rangle} \right) \quad [9]$$

Because s_{hh} is expected to be larger than s_{vv} for drops deformed by drag forces as shown in Figure 1, typical values of Z_{DR} for rain varies from 0 to +4 dB. Snow and ice crystals typically orient themselves horizontally, have large variation in refractive index, and can have large aspect ratios, so Z_{DR} varies from 0 to +5 dB, depending on crystal habit.

Another important polarimetric product is the complex correlation coefficient

$$\rho_{hv}(nT_s) = \frac{\langle s_{vv}([m+n]T_s) s_{hh}^*(mT_s) \rangle}{\langle |s_{vv}(mT)|^2 \rangle^{1/2} \langle |s_{hh}(mT)|^2 \rangle^{1/2}} \quad [10]$$

a measure of the similarities of the time changes in s_{hh} and s_{vv} . The parameter that is most commonly displayed is $\rho_{hv}(0)$, the magnitude at zero lag (typically the magnitude symbols $|x|$ are not displayed). $\rho_{hv}(0)$ is directly computed for STSR mode, but requires further processing and assumptions for the ATSR mode. Because $\rho_{hv}(0)$ is a normalized variable, it is independent of radar calibration. For spherical hydrometeors, $\rho_{hv}(0)$ should be close to unity but can be affected by the quality of the radar hardware (e.g., reflector, feed, etc.) and by the chosen polarimetric data acquisition mode. For more complex scatterer shapes (e.g., tornado debris), $\rho_{hv}(0)$ is reduced from

unity – a fact that can be used for hydrometeor classification and tornado detection, for example.

As stated earlier, we have ignored propagation effects when describing polarimetric products, and have focused on only backscattering effects. Under certain conditions and depending on the radar wavelength, propagation effects can be important. The interested reader is referred to Doviak and Znić (2006) or Bringi and Chandrasekar (2001) for a more complete coverage of the topic.

Examples of Polarimetric Doppler Radar Data

Near the National Weather Center on its research campus, the University of Oklahoma (OU) has a high-resolution, 5-cm-wavelength polarimetric Doppler radar called OU-PRIME for *Polarimetric Radar for Innovations in Meteorology and Engineering* (Palmer et al., 2011, also see Figure 6 insert). The name was coined to emphasize the fact that the radar is used for collaborative research and education in both science and engineering.

On 10 May 2010, a tornado outbreak occurred in Oklahoma producing numerous strong tornadoes. Unfortunately, three deaths were reported along with significant property damage. Several of the more powerful tornadoes formed very near OU-PRIME (less than 1 km) providing polarimetric radar data of unprecedented resolution and quality. An example of the data is provided in Figure 7 in what is called a *plan position indicator* display, where the radar beam is kept at a constant

Figure 7 OU-PRIME measurements of (a) reflectivity factor, Z_h , (b) radial velocity, v_r , (c) differential reflectivity, Z_{DR} , and (d) correlation coefficient, $\rho_{hv}(0)$ at 1.0° elevation angle from the sector scan started at 2245 UTC on 10 May 2010. The radar is located off the lower left of the figure and a 30-km range ring provided for orientation. On panels b, c, and d, a 35-dBz contour line is provided to show features of the various parameters relative to the Z_h field.

elevation angle while rotating in azimuth. For the 10 May case, the four major products of a polarimetric radar are Z_{hr} , v_r , Z_{DR} , and $\rho_{hv}(0)$. The most prominent feature of the reflectivity data (panel a) is the spiral of high reflectivity, the so-called hook echo often associated with a tornado. The tornado itself is likely located at the tip of the 'hook' where there is a small blob of high reflectivity (likely due to tornadic debris) with an 'eye' of lower reflectivity. The radial velocity field (panel b) shows the well-known velocity couplet of out- ($+v_r$) and inbound ($-v_r$) radial velocities (red and green, respectively) caused by the rotation of the tornado. Z_{DR} data (panel c) exhibit very high values (red area, the so-called Z_{DR} Arc; Kumjain and Ryzhkov, 2008), indicative of large drops near the storm's eastern edge. The correlation coefficient field $\rho_{hv}(0)$, shown in panel (d), illustrates the classic debris signature of low $\rho_{hv}(0)$ values near 0.6 at the tip of the hook echo (Ryzhkov et al., 2002).

Through the combination of the various signatures of the polarimetric data, it is possible to greatly improve the performance of tornado detection algorithms and hydrometeor classification techniques. After extensive research with polarimetric radar, operational WSR-88Ds have been recently upgraded to have polarimetric capability. With this advent, new scientific applications are sure to be developed over the coming years.

Future Weather Radar – Phased Array Antennas

The history of weather radar is replete with examples of significant steps forward in technology because of developments for military applications. Prime examples include advances in transmitter technology (e.g., magnetron) and Doppler capabilities. The future of weather radar will very likely show a continuation of this trend.

One technology, which has been used in military radar for decades and is just now being tested in the weather radar community, is electronic beam scanning using *phased array antennas* (Weber et al., 2007; Zrnić et al., 2007). As previously described, conventional weather radars provide complete coverage of storms by mechanically rotating a parabolic reflector antenna. Since the antenna is a very large and heavy structure, it is typically rotated continuously in azimuth and stepped in elevation without rapid starts or stops of the antenna. By doing so, the mechanical stresses on the gears and motors are minimized, prolonging the life of the entire system and reducing maintenance costs. Phased array antennas operate in a completely different way without any mechanical motion.

Each face of a phased array antenna is made up of thousands of individual radiating elements spread over the quasi-circular aperture of the array, which is usually a planar surface (Figure 8). The beam formed by each face azimuthally scans $\pm 45^\circ$ about a vertical plane containing the broadside direction (i.e., the line perpendicular to the array surface). To observe a full 360° coverage, four phased array panels are needed. Each element of the array is a transmitter and receiver and each has a commanded amplitude and phase; the amplitude distribution across the aperture controls the beamwidth and sidelobe levels, and the phase

Figure 8 Artist's depiction of a four-panel planar phased array weather radar (PAR).

distribution controls the direction of the beam. If the phase is uniform across the array, the surface of constant phase of the radiated field is perpendicular to the broadside direction and the beam is along the broadside direction. If the phases of the array elements are adjusted so that the surface of constant phase is tilted relative to the array face, the beam will be pointed in a direction perpendicular to the constant phase surface.

These commanded phase shifts can be generated and changed electronically from pulse to pulse allowing extremely rapid beam steering with no mechanical motion of the antenna. Furthermore, the beam agility provided by electronic steering allows adaptive scanning so the beam needs only scan stormy regions of interest rather than having equal dwell times on regions of clear skies (Heinselman and Torres, 2011). Such a capability for weather PAR exists with the National Weather Radar Testbed – located on the campus of the OU – having a phased array antenna on loan from the US Navy, and a WSR-88D transmitter.

Because of this capability, phased array weather radars (PARs) hold promise for improved observations of rapidly evolving severe weather phenomena. Furthermore, a beam from the same panel but at a different frequency can be pointed in different directions allowing multimission applications (e.g., a single antenna could be used to both observe weather and track aircraft). Also PAR has the capability to operate with more than one beam thus increasing the update rate of data to improve forecasts and warnings (Stensrud et al., 2009; Dawson et al., 2012; Yussouf et al., 2013; Doviak and Zhang, 2013).

As with any new technology, significant challenges exist, such as combining radar polarimetry with phased array antennas. Most military radars use single polarized waves whereas the US NWS has accepted radar with dual polarization capability to better measure rainfall, classify precipitation, and issue warnings. Thus, one such challenge is to develop a polarimetric phased array radar (PPAR) that has equal or better capability than polarimetric weather radars using parabolic reflector antennas. The PPAR (Figure 8) has beamwidths

Figure 9 Artist's depiction of CPPAR with pairs of crossed dipoles for each array element (from Zhang G., Doviak, R.J., Zrnić, D.S., Palmer, R.D., Lei, L., Al-Rashid, Y., 2011. Polarimetric phased-array radar for weather measurement: a planar or cylindrical configuration? *J. Atmos. Oceanic Technol.*, 28, 63–73.). Shown in red (blue) is the $H(V)$ polarized wave and four simultaneous beams are assumed. Beams at other frequencies can be added and steered independently for simultaneous measurements in other missions; thus forming a multi-mission PAR.

and polarimetric wave properties that depend on the direction of the beam and calibration is much more complicated than needed for the existing weather radars (Zhang et al., 2009) The development of PPAR for quantitative weather measurements opens many research opportunities to overcome some of these complexities.

A solution under study is the use of a cylindrical polarimetric phased array radar (CPPAR, Figure 9; Zhang et al., 2011). With this phase array antenna the phases of the elements in a quadrant are adjusted to produce a plane surface of constant phase so that the beamwidth and polarimetric properties are the same independent of azimuth angle. By commutating the amplitude and phase commands around the periphery of the cylinder, the beam scans in azimuth without changes in beamwidth or polarimetric properties. Nevertheless, there are changes in these properties when the beam is elevated, but for weather applications the most important beam directions are those close to the ground and perpendicular to the axis of the cylinder. It remains to be shown that PPAR or CPPAR can exploit their rapid scanning capability while providing weather data with the same quality presently achieved with reflector antennas. This notwithstanding, it is possible that over the next decades PAR will be fully developed and used for operational networks around the world.

Precipitation Radar

SE Yuter, North Carolina State University, Raleigh, NC, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Precipitation radars scan their vicinity to determine the location, intensity, and structure of showers and storms. Several different radar variables are used to determine different aspects of the precipitation. Radar reflectivity measures the number and size of particles. In radars that transmit and receive horizontally as well as vertically polarized energy, differential reflectivity measures the shape of particles and specific differential phase measures the associated liquid water content. Information from the different variables is used to determine hydrometeor type and to estimate rain rate.

Introduction

Precipitation radars are widely used to determine the location, size, and intensity of precipitating storms. Ground-based scanning precipitation radars are used in short-term weather and flood forecasting, and to estimate the distribution and amount of cumulative rainfall over a region. The weather services of many countries have networks of operational radars that monitor precipitation near population centers. The output from these operational radar networks can be combined to provide a picture of the distribution of precipitation over synoptic-scale regions. Mobile precipitation radar on aircraft provides pilots with information to navigate safely around dangerous regions of heavy rain, hail, and turbulence. Precipitation radars are also used to map the three-dimensional structure of storms. Spaceborne precipitation radar on low-orbit satellite maps the structure and distribution of precipitation around the globe over periods of months and years.

The British and Americans first developed weather radar during World War II. The precipitation radar transmits a pulse of electromagnetic energy via an antenna. When the transmitted energy encounters a target, such as a raindrop, part of the transmitted energy is scattered back toward the antenna, where it is received and amplified. The time delay between the original pulse transmission and the receipt of the backscattered energy is used to deduce the distance to the reflector. The relationship between the range-corrected, backscattered, returned power and the size and number of the reflecting targets is the physical foundation for interpreting precipitation radar data.

The frequency of electromagnetic waves f in Hz (s^{-1}) is defined as $f = c/\lambda$, where c is the speed of light and λ is the wavelength in meters. Radar frequencies are divided into several

bands as shown in Table 1. The choice of frequency for precipitation radar is a tradeoff between the practical constraints of size, weight, cost, and the relation between the wavelength and the size of the target hydrometeors. Theoretical considerations favor the choice of the longer S-band and C-band wavelengths for many precipitation applications. However, use of these longer wavelengths is not always practical. The beam width for circular antennas is proportional to λ/d , where d is the antenna diameter. Longer wavelengths necessitate a larger antenna to obtain a focused beam of the same angular beam width. Larger antennas are heavier, require more powerful motors to rotate them, and are more expensive than smaller antennas. Shorter X, K_u , and K_a band wavelengths are often utilized in mobile precipitation radars deployed on spacecraft, aircraft, ships, and trucks where size and weight are more constrained as compared to stationary ground-based radars.

Precipitation Radar Components

The precipitation radar consists of a transmitter, receiver, transmit–receive switch, antenna, and display (Figure 1). In this simplified diagram, the processing of the electromagnetic signals into output suitable for display is included in the display block. A phase detector is often included to measure Doppler velocity. The radar transmitter contains a modulator that switches the transmitter on and off to form discrete pulses. The radar sends out a pulse and then switches to the receiver to “listen” for echoes from precipitation and other atmospheric targets. The range to the targets is obtained by comparing the time of pulse transmission to the time the backscattered pulse is received. In precipitation radars, the pulses are transmitted at a pulse repetition frequency (PRF) of ~ 300 – 1300 Hz and each

Table 1 Precipitation radar frequencies and wavelengths

Band designation	Nominal frequency (GHz)	Nominal wavelength (cm)	Applications
S	2–4	15–8	Surface-based radars
C	4–8	8–4	Mobile and surface-based radars
X	8–12	4–2.5	Mobile and surface-based radars
K_u	12–18	2.5–1.7	Mobile and spaceborne radars
K_a	27–40	1.1–0.75	Mobile and spaceborne radars

Figure 1 Simplified hardware block diagram of a precipitation radar. The non-Doppler portion of the system yields the range r and equivalent reflectivity factor (Z_e) of the target. Dashed lines connect parts of the system included in a Doppler radar that additionally measures the radial velocity of the target (V_r). Adapted from Houze, R.A., 1993. *Cloud Dynamics*. Academic Press, New York, p. 108, © Elsevier.

pulse is on the order of $1 \mu\text{s}$ (10^{-6} s) in duration. The time between transmitted pulses limits the maximum range (r_{max}) the electromagnetic pulse can travel before the next pulse is transmitted.

$$r_{\text{max}} = \frac{c}{2\text{PRF}} \quad [1]$$

The receiver detects and amplifies the received signals and averages the characteristics of the returned pulses over defined time periods. Typical peak transmitted power for operational precipitation radars is 10^5 – 10^6 W. Typical received power is 10^{-10} W. The transmit–receive switch protects the sensitive receiver from the powerful transmitter. Without the switch, the radar transmitter would burn out the receiver. In practice, the transmit–receive switch is not perfect and a small amount of transmitted energy leaks into the receiver.

Radar antennas focus transmitted energy and direct it along a narrow angular beam. For scanning radars, this direction is often described in terms of an elevation angle relative to the ground and an azimuth angle relative to north. Moving the antenna points the axis of the beam in different directions, and permits scanning of two- and three-dimensional regions of the atmosphere. The antenna shape and radar wavelength determines the radar beam size and shape. The magnitude of the radar energy is largest along the center of the beam and decreases outward with increasing angular width. The beam width is defined as the angular width where the power is exactly half the maximum power. Most precipitation radars utilize a circular parabolic antenna for both transmission and reception.

The main purpose of the display is to distinguish scatterers at different ranges. A basic scanning radar display will usually indicate the compass angle and range to the radar echo in polar coordinates. **Figure 2** shows the range-corrected received power as a function of range along a single pointing direction of the antenna. This example illustrates that not all the energy received at the radar is backscattered from meteorological targets. Transmitter leakage and ground clutter from nearby nonmeteorological targets such as trees and buildings are present at close ranges in the display. The signal from a point

Figure 2 Two-dimensional radar display of range-corrected received power as a function of range showing signal from transmitter leakage, ground clutter, point target, and weather echo. See text for further details. Adapted from Rinehart, R.E., 2010. *Radar for Meteorologists*, fifth ed. Ronald E. Rinehart, Fargo, with permission.

target such as a radio tower is present at 50 km range. The wider signal associated with meteorological echo is present between 90 and 115 km range.

The Radar Equation

The radar equation expresses the relationship between the transmitted power and backscattered received power from precipitation targets in terms of the radar's hardware characteristics and the distance between the transmitter and the target. In this section, the radar equation and radar reflectivity will be derived by first making some simplifying assumptions and then gradually refining the terms to more accurately represent the electromagnetic theory underpinning precipitation radars.

Isolated Scatterers

The amount of power incident (P_i) at an isotropic target of cross-sectional area A_t at range r_1 from an isotropic transmitter is

$$P_i = \frac{P_t A_t}{4\pi r_1^2} \quad [2]$$

in which P_t is the transmitted power (**Figure 3(a)**). Transmitted power and received power are commonly expressed in units of watts or dBm. The latter represents the ratio of power (P) in watts relative to 1 mW ($10 \log_{10}[P/10^{-3} \text{ W}]$). In typical operational precipitation radars, the minimum detectable signal is approximately -100 dBm and the peak-transmitted power is ~ 90 dBm.

Assuming the target does not absorb any power and radiates the energy it receives isotropically, the power received at range r_2 from the target by a receiver of effective cross-sectional area A_e (**Figure 3(a)**) is

$$P_r = \frac{P_t A_t}{4\pi r_1^2} \left(\frac{A_e}{4\pi r_2^2} \right) \quad [3]$$

When the transmitted energy is focused with an antenna, the ratio of the power per unit area along the axis of the focused

Figure 3 (a) Schematic of energy from an isotropic transmitter (P_t) traveling distance r_1 to an isotropic target of area A_t . The energy received at the target (P_r) is then isotropically radiated by the target and travels distance r_2 to a receiver of area A_e . (b) In precipitation radars, an antenna is used to focus the energy into a particular direction. The received energy is scattered by the target at range r . The backscattered portion of the energy corresponding to cross section σ is received by the antenna.

beam to the power per unit area of an isotropic transmitter is a measure of antenna gain (g). For a circular, parabolic antenna typically used on precipitation radars, the antenna gain can be approximated as a function of the horizontal (θ_H) and vertical (θ_V) beam widths in radians, or for the receiving antenna as a function of the radar wavelength and A_e .

$$g \approx \frac{\pi^2}{\theta_H \theta_V} \approx \frac{4\pi A_e}{\lambda^2} \quad [4]$$

The antenna gain is usually of large magnitude and is often expressed as the ratio relative to an isotropic antenna in decibel units, $G = 10 \log_{10}(g/1)$. For example, the antenna gain specification is 45 dB for the US National Weather Service WSR-88D operational radars, which means the antenna focuses energy about 30 000 times better than an isotropic transmitter. The use of a directional antenna for transmission leads to modification of the term representing transmitted power in eqn [3] from P_t to $g_t P_t$, where g_t is the gain of the transmitting antenna. Usually, precipitation radars utilize a single directional antenna for both transmitting and receiving which permits the simplifications of $r_1 = r_2 = r$ in eqn [3] and $g_r = g_t = g$.

Real world scatterers are usually not isotropic, and the size of the backscattered cross-sectional area A_t is usually not equal to the physical size of the scatterer. The amount of scattered

energy is dependent not only on the radar wavelength and incident power at the range of the target but also on the target characteristics of size, shape, composition, three-dimensional angle between the target and transmitter, and target velocity. The backscattering cross section (σ) is defined as the apparent area that, if scattered isotropically, would return to the receiver an amount of power equal to the power actually received. Table 2 shows values for σ for diverse types of single scatterers.

Making substitutions for P_t , A_e , and A_t into eqn [3] yields the equation for the power received by a precipitation radar with a directional antenna from a single target of backscattering cross section σ at range r (Figure 3b).

$$P_r = \frac{P_t g^2 \lambda^2 \sigma}{(4\pi)^3 r^4} \quad [5]$$

Distributed Scatterers

Precipitation particles such as raindrops, snowflakes, hail, and graupel act as distributed scatterers in the volume of atmosphere illuminated by the precipitation radar. The resolution volume (V_{res}) illuminated by a transmitted pulse along the beam is approximated by a cylinder defined by the beam widths and pulse length of the radar hardware and range to the volume,

$$V_{res} \approx \pi \left(r \frac{\theta_H}{2} \right) \left(r \frac{\theta_V}{2} \right) \frac{c\tau}{2} \quad [6]$$

in which τ is the pulse length in seconds. Antenna beam widths are assumed to be small, such that the small angle approximation $\theta \approx \sin \theta$ is valid. The resolution volume is defined as the incremental volume along the beam from which scattered energy is received simultaneously at the radar. A one-half pulse length factor (i.e., $\tau/2$), rather than τ , is needed since the backscattered energy from the front edge of the pulse at time $t_o + \tau/2$ and range $r_o + c\tau/2$ arrives back at the radar at the same instant as backscattered energy from the trailing edge of the pulse at time $t_o + \tau$ and range r_o . To account for the actual distribution of power within a beam generated by a circular parabolic antenna, a correction factor of $1/(2 \ln 2)$ is applied to eqn [6] yielding

$$V_{res} = \frac{\pi r^2 \theta_H \theta_V c\tau}{16 \ln 2} \quad [7]$$

For operational precipitation radars, typical beam widths of $1-2^\circ$ and pulse lengths of $0.5-1 \mu s$ result in resolution volumes of order $10^7-10^8 m^3$ at 60 km range.

Table 2 Backscattering cross sections at $\lambda = 10$ cm

Object	$\sigma (m^2)$
C-54 aircraft	10–1000
Human	0.14–1.05
Weather balloon, seagull	10^{-2}
Small birds	10^{-3}
Bee, dragonfly	3×10^{-6} to 10^{-7}
Water sphere ($D = 2$ mm)	1.8×10^{-10}
Free electron	8×10^{-30}

The backscattered signal from a volume of randomly distributed scatterers is the sum of the signals scattered by each of the targets $\sum_{i=0}^n \sigma_i$. The summation of the backscattered cross sections from precipitation scatterers in a unit volume is called the *reflectivity* and is defined as $\sum_{\text{vol}} \sigma_i$. As

individual particles move with respect to one another within the resolution volume, the summation of the signals varies slightly from pulse to pulse. The received power is usually averaged over 50 or more consecutive pulses to yield an estimate that is independent of the fluctuations. The final form of the radar equation implemented in the signal processors of precipitation radars combines eqns [5] and [7] and substitutes the radar reflectivity in the resolution volume, $V_{\text{res}} \sum_{\text{vol}} \sigma_i$, for σ . The radar processor calculates and displays

the averaged received power from the set of scatterers within the resolution volume at a particular range. The equation below is a general form of the radar equation valid for scatterers of all sizes.

$$\bar{P}_r = \frac{P_t g^2 \lambda^2 \theta_H \theta_V c \tau}{1024 (\ln 2) \pi^2 r^2} \sum_{\text{vol}} \sigma_i \quad [8]$$

The 'gate spacing' parameter of the radar processor controls the number and spacing of individual reflectivity estimates along the radar beam. It can be set to a value that combines the signal from several consecutive resolution volumes to increase the effective volume over which the average returned power is computed (eqn [8]). In many radars, the pulse length (τ), PRF, gate spacing, and the number of gates sampled (i.e., maximum range) are variables that can be modified by the radar operator. In scanning radars, the radar operator also specifies the set of elevation angles and range of azimuth angles to be illuminated by the antenna. The specification of the variable radar parameters is called the 'radar scan strategy.'

Association of the Radar Signal to Precipitation Characteristics

Radar Reflectivity of a Volume of Precipitation

To be of value in precipitation studies, the average returned power measured by the radar must be related to the physical characteristics of the precipitation particles within the resolution volume. The backscattering cross section of a single water drop (σ_d) increases monotonically when the diameter D is less than $\sim \lambda/16$ such that

$$\sigma_d = \frac{\pi^5}{\lambda^4} |K|^2 D^6 \quad [9]$$

in which $|K|^2$ is the complex dielectric factor. Equation [9] is referred to as the Rayleigh approximation of the backscattering cross section. When the diameter of the drop, D , is greater than $\lambda/16$ for liquid drops, Mie or optical scattering occurs. In contrast to Rayleigh scattering, under conditions of Mie scattering, the backscattered returned power fluctuates as the size of the scatterer increases (Figure 4).

For precipitation applications, it is preferable to use longer wavelengths to encompass as large a range of raindrop diameters as possible within the scattering regime where the

Figure 4 Normalized backscattering cross-sectional area of a perfectly conducting sphere as a function of circumference divided by radar wavelength λ . Since water drops are not perfectly conducting, the transition from Rayleigh to Mie scattering for the radar reflectivity of spherical water drops occurs at $2\pi r/\lambda \sim 0.2$. From Skolnik, M.I., (Ed.), 1990. Radar Handbook. McGraw-Hill Professional, New York, material is reproduced with permission of the McGraw-Hill Companies.

Rayleigh approximation is valid. By definition, raindrops have diameters >0.2 mm. Most rainfall in midlatitudes consists of raindrops <5 mm in diameter. Drops as large as 8 mm in diameter have been observed but are rare since large drops are unstable and tend to break up into smaller drops. Figure 5 shows the subset of raindrop diameters where Rayleigh scattering occurs as a function of wavelength. Drop size distributions (DSDs) associated with several rain rates are shown for comparison. At S-band, rain rates <10 mm h^{-1} are either entirely or nearly entirely within the Rayleigh regime. The proportion of drops within the raindrop size distribution that are in the Mie region increases with increasing rain rate. Side-by-side radars that matched in all characteristics except wavelength would observe different Z values for a given set of raindrops if the larger drops are within the Rayleigh regime for one radar and within the Mie regime for the other radar.

Figure 5 Comparison of reference raindrop size distributions for 0.5, 1, 5, 10 and 50 mm h^{-1} with range of Rayleigh regime diameters (horizontal bar) for S-band (3 GHz, maximum $D = 6.25$ mm), C-band (5.64 GHz, maximum $D = 3.3$ mm), and X-band (9.4 GHz, maximum $D = 2$ mm) radar frequencies.

Replacing σ_i with σ_d in eqn [8] yields the radar equation for spherical drops under conditions when the Rayleigh approximation is valid.

$$\bar{P}_r = \frac{P_t g^2 \lambda^2 \theta_H \theta_V c \tau}{512 (2 \ln 2) \pi^2 r^2} \sum_{\text{vol}} \frac{\pi^5 |K|^2 D_i^6}{\lambda^4} \quad [10]$$

Equation [10] can be rearranged to group the numerical constants and parameters of the radar hardware together to form the 'radar constant' (C).

$$\bar{P}_r = \left(\frac{P_t g^2 \theta_H \theta_V c \tau \pi^3}{1024 \ln 2 \lambda^2} \right) \frac{|K|^2}{r^2} \sum_{\text{vol}} D_i^6 = C \frac{|K|^2}{r^2} \sum_{\text{vol}} D_i^6 \quad [11]$$

The radar reflectivity factor (Z) is defined as

$$Z = \sum_{\text{vol}} D_i^6 = \sum n_i D_i^6 = \int N(D) D^6 dD \quad [12]$$

The discrete form of the definition is used in calculating Z from *in situ* measurements such as aircraft particle probes or disdrometers that resolve n_i , the number of drops per unit volume of atmosphere, in several discrete diameter intervals. In the continuous definition to the right, $N(D)$ is the number of particles per unit volume in the diameter range D to $D + dD$.

Rearranging eqn [11] yields the definition of Z in units of $\text{mm}^6 \text{m}^{-3}$ in terms of variables measured by the radar, and constants associated with the radar hardware and particular gate spacing.

$$Z = \frac{\bar{P}_r r^2}{C |K|^2} \quad [13]$$

In evaluating eqn [13], a value is needed for $|K|^2$. Precipitation particles consist of water, ice, or a combination of the two. The complex dielectric factor $|K|^2$ is 0.93 for water and 0.197 for ice. Within a particular resolution volume of the radar, the individual meteorological scatterers contributing to Z could be composed of water, ice, or melting ice. The scatterers could also include nonmeteorological targets such as insects, birds, and chaff (i.e., highly reflective man-made scatterers such as thin metal strips). There is no current method to be certain of the value of $|K|^2$. The convention is to assume that all the scatterers are composed of liquid water and to define the equivalent radar reflectivity factor Z_e as

$$Z_e = \frac{\bar{P}_r r^2}{C(0.93)} \quad [14]$$

Table 3 Typical values of observed radar reflectivity factor in various types of precipitation

Radar reflectivity factor (dBZ)	Associated precipitation types
−30 to 0	Marginally detectable precipitation
0–10	Drizzle, very light rain, light snow
10–30	Light to moderate rain and heavier snow
30–60	Moderate to heavy rain
40–55	Graupel
55–70	Hail
30–50	Melting snow particles

By this definition, a single spherical drop with a diameter of 1 mm within a 1 m^3 volume of air has $Z_e = 1$. Equivalent radar reflectivity factor is usually expressed in dBZ such that $\text{dBZ}_e = 10 \log_{10}(Z_e/1)$. It is a common usage to refer to the display of dBZ_e values as 'radar reflectivity factor.' It is usually specified in context whether 'radar reflectivity factor' refers to dBZ or $\text{mm}^6 \text{m}^{-3}$ values. The difference between 30 and 20 dBZ is 10 dB following the decibel convention. The typical ranges of radar reflectivity factor values in different types of precipitation are shown in Table 3.

The difference in dielectric constant between liquid and ice, equivalent to 6.7 dB for a particle of the same size and shape, can be used to detect phase transitions in some circumstances. When rain encounters a sufficiently deep low level layer of air below 0°C it freezes into sleet. Figure 6 shows time–height data from a vertically pointing radar for a storm that produced sleet. The phase transition is shown by the ~ 7 dB reduction of radar reflectivity factor along a time varying boundary between 800 and 2000 m altitude.

The physical interpretation of radar reflectivity factor is more complicated in regions of echo containing mixed phase particles than in regions containing exclusively snow or rain. Partially melted ice particles can have different electromagnetic properties compared to equivalent-sized particles of only ice or water. When snow melts within a narrow layer, a reflectivity maximum in the vertical associated with a concentration of partially melted particles can be discerned if the observing radar has sufficient spatial resolution and sensitivity. This local maximum in reflectivity, just below the 0°C level, is often referred to as a 'bright band.' Figure 7 shows how the apparent width of the bright band increases with increasing range and increasing resolution volume size. Nonuniform beamfilling

Figure 6 Time–height plot of radar reflectivity factor from a vertically pointing K_u -band radar obtained on 13 December 2007 at Stony Brook, NY. The corresponding temperature profile and hydrometeor types are shown on the left. In this example, almost all the rain freezes into sleet yielding a sharp transition in observed reflectivity associated with the changing dielectric constant. Data courtesy of Brian Colle, Stony Brook University.

Figure 7 C-band radar cross section through a wide stratiform precipitation area in the central valley of California on 0148 UTC 3 December 2010. Tick marks are at 10 km intervals. The radar's observation of the melting layer bright band degrades with increasing range from the radar (to the right). Image courtesy of David Kingsmill, University of Colorado, CIRES and NOAA ESRL.

yields high reflectivities in volumes partially overlapping the physical melting layer even though that layer occupies only a portion of the resolution volume.

Beamfilling

The spatial scale of the resolution volume is important in interpreting radar data, since electromagnetic sensors cannot distinguish the spatial distribution of scatterers within a volume. **Figure 8** shows six unit resolution volumes containing different spatial orientations of nine scatterers of the same material, shape, and size. Since radar reflectivity factor (eqn [12]) is only a function of the size and number of the scatterers per unit volume, the radar reflectivity factor values for all six volumes are equal. By convention, it is assumed that the beam is filled with uniformly distributed scatterers (**Figure 8(a)**). Nonuniform beamfilling occurs when the assumption of uniformly distributed scatterers is false. High

Figure 8 Set of six unit resolution volumes (a–f) with the same radar reflectivity factor. All volumes contain the same number of identical targets. The spatial distribution of targets within a radar-observed resolution volume is unknown and is usually assumed to be similar to the uniform distribution shown in (a). (b–f) are examples of nonuniform beamfilling.

time and spatial resolution radar data show that rainfall contains many rapidly varying small-scale structures (**Figure 9**). Corrections for nonuniform beamfilling are an area of active research. These corrections are especially important for large resolution volumes such as those associated with spaceborne radars. An important component of the radar design process is the balancing of the spatial scale of the features of interest and the physical characteristics of the sensor that determine the scale of the resolution volumes.

Attenuation: Energy Losses along the Radar Beam

The path along the radar beam to the target resolution volume and back to the radar contains air molecules and possibly cloud and precipitation particles. These particles absorb and scatter the radar energy, reducing both the incident energy at the target and the backscattered energy arriving at the radar compared to what their values would be if the intervening medium were free space. Attenuation is the total power extracted from the wave and is expressed mathematically as the sum of the power

Figure 9 Fine details of the reflectivity variability within 10 min of S-band vertically pointing radar data obtained on 20 September 1999 at Locarno, Switzerland. Profiles were obtained every second. Taking into account the advection speed of the storm and the radar beam width, a volume corresponding to between 1 and 2 km altitude and 5 min is approximately equivalent to 0.1 km^3 .

absorbed and the power scattered by the intervening particles. Attenuation is a function of radar wavelength, and the size, shape, and composition of the intervening particles. Attenuation accumulates as the wave moves from the radar to the target and back from the target to the radar. Following Beer's law, the incremental reduction in received power with incremental distance ds caused by attenuation is

$$\frac{d\bar{P}_r}{ds} = -2k_L(s)\bar{P}_r \quad [15]$$

in which $k_L(s)$ is the attenuation coefficient (in units of inverse length) over an incremental volume along a path centered at range s . Although $k_L(s)$ is called a coefficient, it is not a constant. Rather it represents the combined influences of attenuation by gases, cloud, and precipitation at a particular location described by range s . The factor 2 is needed since the radar energy travels the same path twice. The received power accounting for the attenuation is the integral solution of eqn [15] from ranges 0 to r .

$$\bar{P}_r = \bar{P}_{r0} \exp\left(-2 \int_0^r k_L(s) ds\right) \quad [16]$$

in which $\bar{P}_{r0}$ is the power that would have been received without attenuation. Attenuation is often expressed as the ratio of the attenuated received power to the nonattenuated received power in units of dB km^{-1} . By utilizing the identity $\log_{10} X = 0.434 (\ln X)$ and defining the specific attenuation as $k(s) = (10 \log_{10} e) k_L(s) = 4.34 k_L(s)$ in units of dB km^{-1} , eqn [16] becomes

$$10 \log_{10} \frac{\bar{P}_r}{\bar{P}_{r0}} = 4.34 \left(-2 \int_0^r k_L(s) ds \right) = -2 \int_0^r k(s) ds \quad [17]$$

The specific attenuation can also be defined in terms of the DSD, and the extinction cross section, $\sigma_e(D)$, which represents the attenuation contributed by a particular particle size D , using

$$k(r) = \int_0^\infty \sigma_e(D) N(D, r) dD \quad [18]$$

in which $N(D, r)dD$ is the number density of hydrometeors per particle size interval dD per unit volume within the incremental volume centered on range r . In practice, specific attenuation is often estimated as a function of the equivalent reflectivity without attenuation $Z_e(r)$.

$$k(r) = \alpha Z_e(r)^\beta \quad [19]$$

in which α and β are coefficients, which are a function of the drop size distribution $N(D)$.

Equation [16] and the definition for $k(s)$, can be incorporated into eqn [13] to yield the equation for the radar reflectivity factor in situations where the attenuation is not negligible.

$$\begin{aligned} Z_e(r) &= \frac{\bar{P}_r r^2}{C|K|^2} \exp\left(2 \int_0^r k_L(s) ds\right) \\ &= \frac{\bar{P}_r r^2}{C|K|^2} \exp\left(\frac{2\alpha}{4.34} \int_0^r Z_e(s)^\beta ds\right) \end{aligned} \quad [20]$$

At radar wavelengths, attenuation by atmospheric gases is dominated by oxygen and water vapor absorption. Gaseous attenuation varies with the radar wavelength, path length, and depth of the troposphere penetrated by the radar beam. Two-way gaseous attenuation curves have been calculated using a standard atmosphere for a range of radar beam elevation angles and radar wavelengths. The overall effect of gaseous attenuation is small at S-band and C-band wavelengths, of order 0.01 dB km^{-1} one way for a 10-cm wavelength radar, but increases as wavelength decreases. A correction for gaseous attenuation is usually made automatically in the radar's signal processor.

The attenuation caused by cloud droplets $<0.2 \text{ mm}$ in diameter is dominated by absorption. For radar wavelengths $\geq 5 \text{ cm}$, attenuation by cloud particles is sufficiently minimal to be ignored. For X-band and K-band wavelengths, the one-way attenuation due to cloud droplets is of the order of 0.1 dB km^{-1} per g m^{-3} liquid water content and is of sufficient magnitude to be of concern. However, unlike the situation with gaseous attenuation, there is no standard model for the distribution of cloud droplets as their distribution is discontinuous and chaotic. Because of the complexities in estimating the actual distribution of cloud particles along a particular radar beam, an automatic correction for attenuation by cloud particles is difficult to implement.

Attenuation in rainfall and snow is a function of the radar wavelength, temperature, particle type, and particle-size distribution. The attenuation in rain can be calculated as a function of reflectivity for specified DSDs, temperatures, and radar wavelengths as shown in Figure 10 and Table 4. At

Figure 10 Specific attenuation versus radar reflectivity at $\lambda = 3.2, 5$, and 10 cm . Computations assume $T = 18^\circ\text{C}$ and Laws and Parson drop size distribution. reflectivities >40 dBZ, which can occur within heavy rainfall, attenuation can become significant at C-band and X-band. S-band energy can become significantly attenuated when passing through regions containing hail or exceptionally heavy rainfall ($Z > 55$ dBZ). **Figure 11** shows a comparison of X-band and S-band reflectivities obtained in a squall line in Oklahoma. While both radars are in reasonable agreement regarding the reflectivity pattern between the squall line and the radar, there is a significant difference in the reflectivity pattern behind the squall line. The attenuated X-band radar reflectivities indicate a much smaller area of precipitation and weaker intensities behind the squall line compared to the non-attenuated S-band data.

Reflectivity by itself provides insufficient information to correct for attenuation since the attenuation is a function of the real rain field that is imperfectly measured because of attenuation. The rainfall attenuation correction is sensitive to the actual distribution of reflectivity and assumptions about the DSDs along the radar beam. Under special circumstances, such as downward-pointing precipitation radars on aircraft and satellites, a reference reflectivity such as the reflectivity of the ocean surface can be used to estimate path-integrated attenuation. Attenuation as a function of range can be

estimated with a dual frequency radar using the differential attenuation between the two wavelengths (**Figure 10**). Corrections based on horizontally and vertically polarized differential phase measurements are also under development. When attenuation corrections are not available, the reduction in reflectivity due to attenuation has to be accounted for in the data interpretation.

Location of the Radar Beam in the Atmosphere

Standard Refraction

The classic formula for refraction is Snell's law, which describes the bending of a light ray at the interface of two media. The ratio of the incident velocity of the wave (V_i) to the refracted velocity of the wave (V_r) is $V_i/V_r = \sin(i)/\sin(r)$, where i is the angle of incidence and r is the angle of refraction. In the earth's atmosphere there is no interface, but the nonuniform vertical distribution of water vapor pressure and temperature refracts the radar beam, changing its direction of propagation compared to a radar beam in free space. The change in direction of the beam is defined in terms of the vertical gradient of the index of refraction dn/dh where $n = c/v$, h is height, c is the speed of light, and v is the velocity of the wave in the medium. At precipitation radar frequencies for a standard atmosphere, $dn/dh \approx -4 \times 10^{-8} \text{ m}^{-1}$, sufficiently large to noticeably bend the radar beam downward compared to its free-space path. The negative value of dn/dh implies that v increases with increasing height.

If the index of refraction were constant with height or zero, the radar beam would curve upward with increasing range relative to the surface of the earth because of the earth's curvature. Precipitation radar data are usually interpreted in a ground-relative frame of reference. The following equation for the height of the radar beam above the earth's surface (h)

Figure 11 Comparison of X- and S-band radar reflectivities in a 1.5° elevation angle scan obtained from side-by-side X-band and S-band radars on 2342 UTC 15 June 2002 in the Oklahoma panhandle. The strong reflectivities within the squall line to the northeast of the radar attenuate the X-band signal (a). The S-band reflectivity data (b) reveal a larger area of precipitation behind the squall line than the X-band radar reflectivity data. Range rings are at 20 km intervals. Image courtesy of Scott Ellis, NCAR.

takes into account both the refraction by a standard atmosphere and the curvature of the earth.

$$h \cong h_0 - \frac{4}{3}R + \sqrt{r^2 + \left(\frac{4}{3}R\right)^2 + 2r\frac{4}{3}R \sin \theta_e} \quad [21]$$

in which θ_e is the elevation angle of the radar beam, h_0 is the height of the radar antenna, r is the slant range from the radar, and R is the radius of the earth at the latitude of interest. The arc distance, s , along the surface of the earth is defined as

$$s \cong \frac{4}{3}R \sin^{-1} \left(\frac{r \cos \theta_e}{\frac{4}{3}R + h} \right) \quad [22]$$

Figure 12 shows the radar beam center height (shaded lines) and beam width relative to the arc distance along the earth's surface for a US National Weather Service precipitation scan strategy (0.95° radar beam width and elevation angles: 0.5, 1.45, 2.4, 3.35, 4.3, 6.0, 9.9, 14.6, 19.5°). The radar location is indicated by the circle at 0 km height. Standard atmospheric refraction and the earth's curvature have been taken into account to calculate the beam path following eqns [21] and [22].

Figure 12 Radar beam center height (shaded lines) and beam width relative to the arc distance along the earth's surface for a US National Weather Service precipitation scan strategy (0.95° radar beam width and elevation angles: 0.5, 1.45, 2.4, 3.35, 4.3, 6.0, 9.9, 14.6, 19.5°). The radar location is indicated by the circle at 0 km height. Standard atmospheric refraction and the earth's curvature have been taken into account to calculate the beam path following eqns [21] and [22].

Figure 13 Ray paths in arc distance coordinates for radar beams in conditions with a standard atmosphere (dashed line) and for an atmosphere with a temperature inversion from the surface to 100-m altitude (solid lines). The arc distance coordinate compensates for the curvature of the earth and atmospheric refraction such that the ray path for the elevation angle $\theta_e = 0.4^\circ$ for a standard atmosphere is shown as a nearly straight line (dashed line). In comparison, ray paths for 0.4° and lower elevation angles in conditions with a low-level temperature inversion are refracted toward the surface. The lower the elevation angle, the greater the distance the ray path traverses within the 100-m thick inversion, and the greater the refraction of the beam downward.

moisture and temperature inversions and hence nonstandard refraction include nocturnal radiation cooling, advection of warm dry air over cooler bodies of water, and downdrafts of cool moist air that reach the surface within precipitating storms.

When the radar beam undergoes superrefraction, the height of the radar resolution volume at a particular range is lower than it would be under conditions of standard refraction. A radar beam elevation angle that usually clears nearby mountain peaks may intersect them under conditions of nonstandard refraction. A radar echo at a mountain peak can be difficult to discern as a nonmeteorological echo associated with anomalous propagation, as it is common for orographic precipitation to form over mountain peaks. In the extreme case, when the ray path is pointed into the ground, a strong echo, associated with the large cross section of the earth's surface, appears on the radar display.

A characteristic of nonmeteorological echo associated with anomalous propagation is that these echoes are relatively stationary compared to echoes associated with precipitating storms. A comparison of low elevation radar scans from several consecutive times can often reveal anomalous propagation. Automatic detection and removal of nonmeteorological echo associated with anomalous propagation includes methods involving polarization radar variables.

Polarization Variables Associated with Precipitation Estimation

Small raindrops, <1 mm in diameter, are spherical. Larger raindrops are deformed by aerodynamic drag into horizontally oriented oblate spheroids. An oblate spheroid is the body of revolution formed when an ellipse with minor axis dimension (a) and major axis dimension (b) is rotated about its minor axis. Raindrops usually fall with their maximum dimension oriented horizontally. This orientation may be temporarily disturbed by

turbulence, drop collision, or aerodynamic instability. The ratio between the horizontal and vertical dimensions of larger drops results in different electromagnetic properties of the scattered energy when the incident energy is horizontally versus vertically polarized. A special type of precipitation radar, called a polarimetric radar (also known as polarization diversity radar), is designed to measure these properties by transmitting and receiving radiation in more than one polarization. Ongoing research has shown that polarization radar variables involving the differential amplitude and phase of the received power at orthogonal polarizations can be related to the physical characteristics of the precipitation. Of these variables, two commonly used in precipitation applications are differential reflectivity (Z_{DR}), related to the axis ratio of the precipitation particles, and specific differential propagation phase shift (K_{DP}), which is a function of the concentration, composition, and size of only the anisotropic particles in a sampling volume.

Differential Reflectivity

To obtain radar reflectivity, energy is transmitted and received at the same polarization, usually horizontal. Differential reflectivity is the difference between the horizontally transmitted, horizontally received reflectivity factor (Z_{HH}) and the vertically transmitted, vertically received reflectivity factor (Z_{VV}).

$$Z_{DR} = 10 \log_{10} \frac{Z_{HH}}{Z_{VV}} \quad [23]$$

Differential reflectivity is a measure of the reflectivity-weighted mean axis ratio (a/b) of precipitation particles in a resolution volume. As raindrops increase in volume, D increases, the shape of the drop becomes more oblate, the axis ratio decreases, and the associated Z_{DR} value increases. For spherical raindrops or spherical ice particles, the axis ratio $a/b = 1$ and $Z_{DR} \sim 0$. Of particular importance to precipitation studies is the capacity of Z_{DR} obtained at nearly horizontal elevation angles to distinguish among regions containing rain, hail, and graupel, and the layer of melting snow particles above the rain layer. Table 5 describes typical Z_{DR} values associated with several basic precipitation types. Z_{DR} is also a function of the dielectric constant and hence composition of the particle. For a given axis ratio, the Z_{DR} value of a raindrop will be larger than for an ice particle of the same size. Graupel and hail particles usually either tumble or are axially symmetric and have an associated Z_{DR} value near 0. Negative values of Z_{DR} have been reported for regions containing hail and graupel but the detailed

Table 5 Typical ranges of observed differential reflectivity values in several types of precipitation

Differential reflectivity (dB)	Associated precipitation types
−0.5 to 0.5	Marginally detectable precipitation
−0.5 to 0.5	Drizzle, very light rain, light snow
>1	Moderate rain and heavier snow
0.5–4	Moderate to heavy rain
−2 to 0.5	Hail and graupel
0.5–4	Melting snow particles

Adapted from Doviak, R.J., Zmric, D.S., 2006. Doppler Radar and Weather Observations, second ed. Dover Publications, New York; Straka, J.M., Zmric, D.S., Ryzhkov, A., 2000. Bulk hydrometeor classification and quantification using polarimetric radar data: synthesis of relations. Journal of Applied Meteorology 39, 1341–1372.

physics underlying these measurements is not well understood. Melting snow appears to the radar as large particles with the dielectric properties of water. These particles often have very large axis ratios and large Z_{DR} values.

Differential reflectivity is independent of the absolute radar calibration since it is the difference between Z_{HH} and Z_{VV} but it is sensitive to relative calibration. In practice, Z_{HH} and Z_{VV} are often measured by parallel hardware with different calibration constants necessitating two calibration measurements. When viewed vertically, raindrops of all sizes appear circular and have an associated Z_{DR} value equal to 0. A Z_{DR} bias, accounting for the relative difference in calibration between the H and V polarizations can be estimated by pointing the radar beam directly upward in rain.

Differential Phase Variables

As an electromagnetic wave traverses a precipitation-filled volume, incident energy is scattered back toward the radar and forward along the beam. The forward scattered (propagated) component of the wave acquires a phase shift compared to the free-space component of the wave transmitted from the radar. Within horizontally oblate raindrops, the propagating horizontally polarized wave undergoes a larger phase shift per unit length and travels more slowly than the vertically polarized wave. After passing through a volume filled with horizontally oblate raindrops, the horizontally polarized wave will have a larger propagation phase shift than the vertically polarized wave (Figure 14). The one-way differential propagation phase (ϕ_{DP}) is defined as the difference between the propagation phase shift of the horizontally transmitted, horizontally received energy (ϕ_{HH}), and the propagation phase of the vertically transmitted, vertically received energy (ϕ_{VV}).

$$\phi_{DP} = \phi_{HH} - \phi_{VV} \quad [24]$$

As the radar wave traverses a region of precipitation filled with oblate drops, ϕ_{DP} accumulates with increasing range. To remove range effects, ϕ_{DP} is differentiated with respect to r to yield specific differential propagation phase (K_{DP}) in units of degree per kilometer.

$$K_{DP} = \frac{d\phi_{DP}}{dr} \quad [25]$$

Often measurements of ϕ_{DP} are noisy and K_{DP} is integrated over several kilometers to obtain a usable signal.

K_{DP} values can be related to the liquid content and axis ratio of the drop by the following equation.

$$K_{DP} = \left(\frac{180}{\lambda} \right) 10^{-3} cW \left(1 - \left[\frac{a}{b} \right]_m \right) \quad [26]$$

in which λ is the radar wavelength, $c \sim 3.75$, W is the liquid water content in g m^{-3} , and $(a/b)_m$ is the mass-weighted mean axis ratio. For a given liquid water content, K_{DP} increases with decreasing radar wavelength within the precipitation radar frequency band. K_{DP} is not affected by attenuation since it is based on the measurement of the phase shift of the wave rather than the amplitude of the returned power. This basis on phase shift allows a K_{DP} signal to be obtained when the radar beam is partially blocked such as in mountainous terrain. Applications of K_{DP} include distinguishing the rain portion of rain–hail

Figure 14 Sketch of the propagation phase shift of horizontally and vertically polarized electromagnetic waves passing through a precipitation-filled radar resolution volume. Left column shows the horizontally (H) and vertically (V) polarized waves prior to entering the resolution volume (middle column). Right column shows the H and V polarized waves after leaving the resolution volume. The H and V polarized waves are assumed, for this example, to be in phase prior to entering the resolution volume. (a) When the waves encounter a resolution volume containing horizontally oblate raindrops, the phase of the horizontally polarized wave is shifted more than the vertically polarized wave and $\phi_{DP} \neq 0$. (b) When the waves encounter spherical particles such as small raindrops or hail, the H polarized wave and V polarized wave are shifted the same amount and $\phi_{DP} = 0$.

Table 6 Typical ranges of observed S-band K_{DP} values in several precipitation types

K_{DP} ($^{\circ}\text{km}^{-1}$)	Precipitation types
–0.5 to 0.5	Marginally detectable precipitation
–0.5 to 0.5	Drizzle, very light rain, snow
–0.5 to 1	Moderate rain
0.5 to 5	Moderate to heavy rain
–0.5 to 1	Hail
–0.5 to 1	Melting snow particles

Cambridge University Press, Cambridge.

mixtures and estimating the liquid water content of oblate raindrops. A disadvantage of K_{DP} is its insensitivity to precipitation composed of small spherical raindrops, where $D < 1$ mm and $a/b = 1$, associated with low liquid water contents and low rain rates. Table 6 describes typical S-band K_{DP} values of several basic precipitation types.

Precipitation Characterization and Estimation from Radar Data

Hydrometeor Classification

Combining complementary information from radar-observed variables can yield more information on hydrometeor types than a single variable alone. As described above, Z provides information on the size and number of particles, Z_{DR} values are

a function of particle shape (axis ratio) and size, and K_{DP} is proportional to liquid water content in rain and melting hail.

The combination of Z and Z_{DR} is often used to distinguish hail from heavy rain. This distinction is important for operational warnings as well as for rain mapping. Figure 15 shows a commonly used hail parameter called HDR. Radar data with values of Z and Z_{DR} above the line are classified as hail while those below the line are classified as rain. This figure also illustrates the impact of Mie scattering (resonance) on Z and Z_{DR} values at C-band (5.64 GHz) and X-band (9.4 GHz). The dots represent Z and Z_{DR} values computed from observed DSDs. Using the S-band (3 GHz) dots as representing values in the Rayleigh regime, one can see that resonance effects yield larger Z_{DR} values for a given Z value particularly at C-band.

An application of hydrometeor classification is shown in Figure 16. The different columns show Z , Z_{DR} , K_{DP} , and hydrometeor classification for an intense summer storm in Colorado. At the initial time (Figure 16, top row) near $x = -15$ km and $y = -40$ km, there is an area of heavy rain ($Z \sim 57$ dBZ and $Z_{DR} \sim 2.3$ dB) with a high liquid water content ($K_{DP} \sim 3.4^{\circ}\text{km}^{-1}$). Eleven minutes later (Figure 16, bottom row), the high Z region has intensified to greater than 60 dBZ and shifted slightly to the south. The corresponding near zero Z_{DR} value indicates large hail. The locally heavier rainfall (K_{DP} local maximum) is slightly to the north of the hail core.

Rainfall Mapping with Precipitation Radar: Role of the Raindrop-Size Distribution

As described in the sections above, measured precipitation radar variables can be related to several parameters of the

Figure 15 Computed Z_{DR} versus Z_{HH} for three frequencies based on observed drop size distributions obtained in Locarno, Switzerland during September and October 1999. The wider spread of points at C-band (5.64 GHz) compared to S-band (3.0 GHz) and X-band (9.4 GHz) indicates stronger resonance at C-band for $Z > 35$ dBZ. The line marked HDR indicates the boundary between hail (above the line) and rain (below the line) based on the combined Z and Z_{DR} hail identification parameter. raindrop size distribution $N(D)$. The raindrop size distribution is generally accepted to be a truncated exponential function of the form,

$$N(D) = N_0 D^\mu \exp(-3.67D/D_0) \quad [27]$$

in which D is the diameter of a spherical drop with volume equal to that of the actual raindrop, μ has a value between -3 and 8 , D_0 is the median volume diameter of the distribution, and N_0 is a function of D_0 , μ , and the total drop concentration. DSDs and drop shapes have been measured and modeled. These studies have yielded a range of values for and a range of relationships among N_0 , D_0 , μ , and the drop axis ratio as a function of D . These uncertainties translate into uncertainties in relations among parameters of $N(D)$.

Moments of the DSD can be related to one another by an equation of the form, $\bar{y} = \alpha \bar{x}^\beta$, where x and y are different moments of the DSD, and α and β are real-valued coefficients. Table 7 lists several moments of the DSD. The most commonly applied association between moments of the DSD is the Z – R relation, which translates the variability of the DSD as measured by the radar in terms of Z in $\text{mm}^6 \text{m}^{-3}$, into variability in terms of the desired quantity R in mm h^{-1} . The Z – R relation is traditionally expressed in the form $Z = aR^b$, although Z is the independent variable. There are numerous Z – R mappings in the literature. Each relation is based on different empirical data sets, methodologies, and assumptions regarding the coefficients in eqn [27]. Some selected relations are shown in Table 8. The Z -conditional relative uncertainty in rain rate varies from ~ 10 to 50% as a function of Z for the four Z – R relationships in Table 8. These Z -conditional uncertainties represent a combination of several error sources and differences in precipitation among regions. Z – R methods usually truncate input Z at ~ 55 dBZ to mitigate large errors in estimated rain rate associated with hail.

Alternate methods to map rainfall using S-band, C-band, and X-band radar data utilize measurements of Z_{DR} and K_{DP} in addition to, or in place of, Z . K_{DP} is related to the fourth moments 4.24–5, depending on a number of factors of the

DSD and can be used to estimate R using a power law of the form $\bar{y} = \alpha \bar{x}^\beta$. Other methods employ several simultaneously measured parameters of the DSD to constrain the coefficients in eqn [27]. The derived DSD is used in turn to estimate the desired parameter R . Several assumptions, with attendant uncertainties, are needed to make the associations among the

polarimetric radar-measured bulk properties and the functional form of the DSD. Use of either Z_{DR} or K_{DP} to constrain the DSD coefficients requires assumptions about the drop axis ratio as a function of D . Neither Z_{DR} nor K_{DP} are sensitive to the small spherical drops within the DSD, so the distribution of the smaller drops must be assumed as a function of the derived

Table 9 Factors contributing to uncertainties in rainfall mapping from precipitation radar data. The magnitudes are for operational scanning radars with typical resolution volumes of 1 km^3 . The trend in uncertainty with increasing range is defined in terms of the same meteorological or nonmeteorological circumstance being present at closer versus farther ranges from the radar

Type of error	Factor	Nature of effect and situations where it is significant	Trend of uncertainty with increasing range from radar
Noise	Precision of measured $\bar{P}_r$	Varies with PRF and scan rate. Typically $\sim 1 \text{ dB}$.	Not a function of range.
Persistent bias	Calibration of $\bar{P}_r$	Typically $\sim 2 \text{ dB}$ for calibrated radars. Depends on priorities and resources.	Not a function of range.
Persistent bias	Changes in DSD between lowest radar measurement and the surface	Varies between 0 and 3 dB km^{-1} depending on vertical structure of precipitation.	Generally increases with height difference between lowest radar beam and the ground. Increases with range.
Persistent bias	Ground clutter and beam blockage	Varies with radar site and its relation to regional geography.	Shielded area increases with increasing range.
Intermittent bias	Signal enhancement by melting particles	Partially melted particles have Z values 1–5 dB larger than completely melted particles.	Effect limited to ranges where radar beam intersects melting layer.
Intermittent bias	Anomalous propagation	Associated with temperature and moisture inversions. Changes beam height in relation to its standard atmosphere value. In extreme, beam intersects ground yielding high Z value.	Magnitude increases with smaller beam elevation angles, increasing range, and increasing strength of inversion.
Intermittent bias	Nonmeteorological echo such as sea clutter, birds, and insects	Increases Z above its meteorological value. In extreme, indicates presence of heavy rain when there is none present.	Generally decreases with range, as beam is located higher from near surface sources.
Intermittent bias	Presence of hail	Increases measured Z to value 4–10 dB higher than that of associated rainfall.	Decreases once resolution volume becomes larger than pocket of hail.
Intermittent bias	Strong downdrafts	Increase R for same Z . Equivalent to reducing Z by 3–5 dB.	Decreases once resolution volume becomes larger than downdraft.
Intermittent bias	Attenuation	Reduces measured Z from its actual value. Increases with decreasing wavelength. Varies with distribution of precipitation along radar beam.	Accumulates with range.
Intermittent bias	Z -conditional variations in the DSD	Often difficult to isolate from other systematic errors. Uncertainty equivalent to variations in $Z \leq 2.5 \text{ dB}$.	Decreases with increasing size of resolution volume.

distribution of the larger oblate drops. Additional assumptions regarding the variability of the coefficients in the DSD, particularly μ , are often utilized.

Practical Issues Contributing to Rain Map Uncertainty

The quantitative estimation of errors associated with rain mapping from radar data is severely hampered by the lack of an independent, precise, and accurate value with which to compare. Additionally, rapidly changing conditions within precipitating storms make it difficult to repeat a measurement under the same conditions. Independent sources of random and systematic error in rain mapping are described in Table 9. Error sources for polarimetric methods are similar with a few exceptions. Z_{DR} and K_{DP} measurements are not biased by the presence of hail. K_{DP} is not influenced by attenuation. Both Z_{DR} and K_{DP} are sensitive to mild nonstandard refraction such that the height of the radar beam is lower in the atmosphere compared to its height in a standard atmosphere. Methods using polarimetric variables can detect when the nonstandard refraction is sufficiently strong such that the radar beam intersects the ground.

An additional source of uncertainty is associated with nonuniform beamfilling (Figure 8). For example, when an isolated 1 km^3 raining cell is contained within an otherwise

empty 8 km^3 resolution volume, the measured reflectivity for the entire resolution volume will be much smaller than the reflectivity within the isolated raining cell. When the resolution volume is not uniformly filled (i.e., rain is not homogenous in the volume), an uncertainty arises when computing the average rain rate from the average reflectivity. The reason is that while $\bar{y} = \alpha \bar{x}^\beta$, $\bar{y} \neq \alpha \bar{x}^\beta$ for $\beta \neq 1$, as is usually the case for Z - R relations. This type of uncertainty is of concern when computing R from Z for volumes that are larger than the scale of the rainfall variability (Figure 9) and when comparing different moments of the DSD obtained at different spatial resolutions, for example, ground-based radar and satellite passive microwave measurements, or radar and rain gauge data.

A comparison of the relative uncertainties associated with several independent sources of error in rain mapping is shown in Figure 17. The data shown are related to the monthly rainfall accumulation for October 2000 for the region centered on Kwajalein Atoll, Marshall Islands. In this analysis, uncertainties associated with the radar calibration, the Z - R relation, and a vertical profile correction are treated separately. Figure 17(a) shows a best estimate of monthly rainfall. The other panels represent the difference between high and low values for the particular source of uncertainty. There is a large variation in

Figure 17 Monthly rain accumulation and uncertainties derived from reflectivity data collected by the KPOL S-band radar on Kwajalein Island, Marshall Islands for October 2000. Average accumulation over the region is shown in the lower right of each panel. (a) The best estimate for the month. The other panels show the difference between maps computed with (b) high (+2 dB) minus low (−2 dB) estimates of the calibration correction, (c) high ($Z = 160R^{1.5}$) minus low ($Z = 190R^{1.5}$) estimates of the Z - R relationship, and (d) high minus low estimates of a vertical profile correction. The difference maps are computed by using the best estimates of all factors except the one considered in that panel.

rainfall accumulation (regional average 176 mm) associated with small uncertainties in the radar calibration, in this case ± 2 dB (Figure 17(b)). The difference between different vertical profile corrections increases with increasing range, with the largest variations at the outer ranges of the domain (Figure 17(d)). In comparison, the uncertainty in Z – R relations derived from *in situ* drop size measurements obtained with a disdrometer are a smaller source of error (Figure 17(c), regional average = 34 mm).

Introduction

Synthetic aperture radar (SAR) images are produced by an active system that sends a microwave signal from a sensor platform to the ground and detects backscattered waves that the ground reflects directly back to a receiver on the same platform, which can be borne aloft by either airplanes or satellites. When the source and receiver are on the same platform, the radar is said to be monostatic. If the source and receiver are on different platforms, the radar is said to be bistatic. Commercial SAR systems are monostatic and always collect images to the side of the flight path of the sensor platform, unlike most multispectral imaging systems, which commonly look straight down and are passive (consisting only of receivers of reflected sunlight and emitted thermal infrared radiation). Figure 1 demonstrates these three different viewing geometries.

Although the currently available commercial SAR satellites, ERS-1 and Radarsat, send and receive only one frequency of microwaves, it is possible to build multifrequency SAR systems that send and receive several frequency ranges of radar signals simultaneously, similar to the way multispectral scanners collect several spectral bands of visible, reflective infrared, and thermal infrared wavelengths simultaneously. SAR systems that send out both horizontally and vertically polarized microwaves and receive both the horizontally and vertically polarized reflected components of each type of incident signal on the ground are called multipolarization radars. Most multispectral systems ignore polarization measurements of reflected sunlight and emitted thermal infrared radiation, although both are present in the passive signals coming from the ground. This article is devoted to applications of multifrequency and multipolarization radars, which have been used much less frequently than monofrequency SAR data in the past. However, future uses of multifrequency and multipolarization SAR systems are likely to increase, owing to their greater information content compared to monofrequency SAR systems, as this article will demonstrate.

Comparison of Multifrequency SAR with Multispectral, Short-Wavelength Images

Visible wavelengths (0.40–0.67 μm) of electromagnetic radiation from sunlight interact with the outer electron shells of transition metal ions in pigments, and thermal infrared wavelengths (4–14 μm) of heat emitted from objects on the Earth's surface interact with ions bound in crystalline lattices (Vincent, 1997). Thus, variations in the way electromagnetic radiation is reflected from or emitted by an object on the Earth's surface as a function of wavelength yield information about the chemical composition of the object, though visible light tells mostly about trace element content and thermal infrared radiation tells more about the bulk chemistry of the object. SAR systems employ microwave wavelengths (in the centimeter-to-meter range) that are at least 1000 times longer than even thermal infrared radiation, so radar waves cannot interact well either with pigments or with the crystalline structure of natural materials. Consequently, radar images contain much less information about chemical composition of an observed object than do either thermal or visible images.

However, radar images are much more sensitive than infrared or visible images to two parameters of an observed object: water content and physical extent (size and shape) of the object. These are the parameters for which microwaves (and radar images) have an advantage over all other wavelengths of electromagnetic radiation. Before they are discussed in the next two sections, however, it is instructive to review the relationship between wavelength and frequency for electromagnetic radiation, of which microwaves are examples. From the elementary physics equation of distance equals the velocity $\times$ time (or period, which is the reciprocal of the frequency), the relationship between wavelength and frequency of electromagnetic waves is given by eqn [1].

$$\lambda = \frac{c}{\nu} = \frac{30 \times 10^9 (\text{cm s}^{-1})}{\nu (\text{s}^{-1})} \quad [1]$$

Figure 1 Viewing geometry for signal source (S) and receiver (R) for (a) bistatic radar, where source and receiver are on different platforms (any angle between S and R is acceptable, as long as R and S are both above the ground); (b) monostatic radar, where source and receiver are on the same platform; and (c) passive receiver for visible/infrared sensors of a LANDSAT satellite.

where ν is the frequency in cycles per second, or hertz, and c is the velocity of light (cm s^{-1}), which is the velocity at which all electromagnetic waves travel, including microwaves. For example, a microwave of frequency 1 GHz (10^9 Hz or 1 GHz) has a wavelength of 30 cm (within the range of L-band radar), and a microwave of frequency of 10 GHz has a wavelength of 3 cm (within the range of X-band radar). Thus, multifrequency (many frequencies) and multispectral (many wavelengths) are synonymous adjectives of radar.

The Effect of Water Content of an Observed Object on Radar Backscatter

Because water has a very high dielectric constant for most microwave wavelengths, it reflects microwaves very efficiently as a specular reflector, i.e., such that most reflection is off the first surface and the angle of reflectance equals the angle of incidence. Calm, standing water reflects almost all incident microwaves forward at the specular angle (equal to the angle of incidence), and reflects almost none of them in the direct

backscatter direction (where the receiver is located for SAR images), which makes calm water appear very dark in SAR images, regardless of the wavelength or frequency of the radar.

The effect of variations in water content of soils, or soil moisture (located above the water table), on radar backscatter is not as simple as in the case of standing water. Fortunately, this subject has been well addressed in a paper by Mancini and colleagues (see [Further Reading](#)) that reports on a laboratory experiment on the use of active microwave observations to estimate volumetric soil moisture content within an accuracy of 5%. A sandy loam with two surfaces (smooth and rough) was wetted and dried to generate different soil moisture profiles (with depth), and radar measurements were made at three different incidence angles (11° , 23° , and 35°) over a frequency ranging from 1 to 10 GHz, with 11.25 MHz step in frequency. [Figure 2](#) shows the resulting plots of radar backscatter coefficient versus frequency of the microwaves for both rough and smooth surfaces of the sandy loam at 11° and 35° angles of incidence, where w14 refers to the end of a wetting profile (water being added) that resulted in a 22.9% moisture content at a depth of 2.5 cm; d13 is a drying profile (water being

Figure 2 Radar data for smooth and rough surfaces with the extreme moisture conditions for 11° incidence angle and 35° incidence angle. Reproduced with permission from Mancini, M., Hoeben, R., Troch, P.A., 1999. Multifrequency radar observations of bare surface soil moisture content: a laboratory experiment. *Water Resources Research* 35 (6), 1827–1838.

removed by evaporation) ending with a 1.9% moisture content at a depth of 2.5 cm; w22 is a wetting profile ending with a 17.8% moisture content of 10.6% at a depth of 4 cm; and d26 is a drying profile ending with a moisture content of 10.6% at a depth of 4 cm.

Although the two left-most plots in [Figure 2\(a\) and 2\(c\)](#) demonstrate that at an angle of incidence of 11° there is a large difference between wet and dry soils, they also demonstrate that there is little frequency dependence in that difference. Thus, for an incidence angle of 11° (relatively small incidence angles), it is possible to determine soil moisture equally well at all frequencies. Multifrequency radar offers no advantage for soil moisture estimations from SAR measurements. However, the absolute value of the ratio of the difference between the backscatter coefficients at 5 and 2.5 GHz and the sum of the same two backscatter coefficients is much greater for the smooth surface than for the rough surface for all reported values of soil moisture. This indicates that multifrequency radar at low incidence angles could be used to determine relative surface roughness, regardless of soil moisture.

The top-right plot in [Figure 2\(b\)](#) shows that when smooth surfaces are viewed at higher incidence angles (35° in this case), specular reflection dominates volume reflection for frequencies greater than 6 GHz, and soil moisture no longer has much effect on the backscatter coefficient. Volume reflection dominates the rough surface reflection at an incidence of 35° , just as it did with both the smooth and rough samples of the 11° incidence measurements. In all cases above, wetter soils return more backscattered microwaves than drier soils at all frequencies, for a given surface roughness and incidence angle. When volume reflection dominates, as it does in all of [Figure 2](#) except for the smooth, 35° incidence case ([Figure 2\(b\)](#)), backscatter rises with increasing frequency, up to approximately 5 GHz. Lower incidence angles correspond to higher direct backscatter. The greatest signal return from soils, wet or dry, toward a monostatic radar receiver can be obtained by a low incidence angle and a frequency of approximately 5 GHz, as indicated by the results of the study of Mancini and colleagues.

Another feature in [Figure 2](#) is the oscillatory pattern in the backscatter coefficient as a function of frequency, which is especially obvious in the lower left plot ([Figure 2\(c\)](#)) for a rough surface viewed at an incidence angle of 11° . Mancini and colleagues claim that this is not caused by noise and state that it might be caused by the volume scattering component of the reflectance interfering with the specular reflectance component from the surface. If so, it would be possible to relate this oscillation to an observation depth, as discussed by Troch and colleagues. Therefore, multifrequency radar may be able to determine the observation depth of a soil through the oscillatory nature of the backscatter coefficient as a function of frequency. More research is needed to confirm this potentially important application of multifrequency radar.

The Effect of Size and Shape of an Observed Object on Radar Backscatter

The second parameter for which radar is more sensitive than visible or infrared radiation is the physical extent (size and

shape) of an observed object. In geological terms, size is the difference between gravel, cobblestones, and boulders on the surface. When the object is a layer of soil or rock, the thickness of the layer is considered to be its 'size.' Visible and reflective infrared electromagnetic radiations have wavelengths of the order of 0.5–4.0 mm, within the size range of clay-sized particles but not of sand-sized grains (about 60–1000 mm in size). Penetration of an electromagnetic wave into typical Earth materials will be on the order of a few wavelengths, which means that visible and infrared radiations typically penetrate rocks and soils less than the diameter of a human hair, which is approximately 100 mm. Microwaves, however, have much longer wavelengths than visible and infrared radiations, on the order of 1 cm to 1 m. They can interact with the shapes and sizes of gravel, cobbles, and boulders in different ways, depending on whether the wavelength of the microwaves selected for the radar is X-band (about 3 cm), L-band (about 30 cm), or P-band (about 70 cm). Microwaves can also penetrate dry soils to depths of meters, with greater penetration by longer wavelength radiation.

Louis Dellwig reported on the earliest investigations into the application of multifrequency radar to geological mapping more than three decades ago. He compared airborne radar images of K-band (sub-cm), Ka-band (0.84 cm), C-band (6.73 cm), and P-band (70 cm) wavelengths, collected at different times over an arid area near Písgah Crater, California. He made two significant observations from the multifrequency radar data set. First, he noted that windblown silts and sands were penetrated by the long-wavelength radar (P-band), which was reflected by the partly buried basaltic lava underneath. The shorter wavelength radar did not penetrate these aeolian deposits. Second, he noted that an alluvial fan with a surface composed of rock fragments that were mostly (85%) less than 5 cm in diameter was dark-toned (smooth) in the P-band radar image, but was bright and well-defined (rough) on the K-band radar image. This investigation ably demonstrated that longer wavelength radars penetrate deeper and are largely unaffected by pebbles and cobbles at the surface.

The author's PhD thesis was in this same Písgah Crater area; and in 1972, Ben Drake (a fellow geologist at Willow Run Laboratories of the University of Michigan, which became ERIM in January of 1973) simultaneously collected X-band and L-band images of the Lavic Lake region, which were field tested. At dark spots on the L-band images (where nothing appeared in the X-band images) were found ancient, hand-dug wells around the periphery of Lavic Lake (a dry lake), with abundant Native American pottery shards near them. It was assumed that the L-band radar had detected the top of the shallow water table. It was also noted that a basaltic lava outcrop in the dry lake with no visible connection to the main Písgah Crater lava flow had an apparent connection in the L-band image, but not in the X-band image. Only half a meter could be dug with a manual post-hole digger and dynamite was used to blast down to approximately 1.5 m, but the buried lava tube, the presence of which was believed to be there (but not proved), was never found. Dellwig's conclusion that "the real value of long-wavelength radar... is not its penetrative capability or any other single factor per se, but its unique total response to terrain characteristics, as compared to a shorter wavelength radar system" was agreed upon.

Much more recently, Abdelsalam and Stern reported on a NASA Space Shuttle Space Radar Laboratory experiment that simultaneously collected L-band (24 cm), C-band (6 cm), and X-band (3 cm) SAR data over the Sahara and Arabian deserts. They were able to locate the Keraf Suture, where an ancient collision between the Nubian Shield and the Nile Craton once occurred. The suture had not previously been mapped because windblown sand obscured it at visible and infrared wavelengths. They also found that the multifrequency radar data were able to separate igneous rocks, Cretaceous-aged sedimentary rocks, and Precambrian basement rocks for geological mapping, owing to their variations in surface roughness at these three wavelengths of active microwave radiation.

Vegetation can also provide differences in surface roughness that multifrequency radar can map. Podwysocki and colleagues found that Ka-band (0.86 cm) and X-band (3.5 cm) images displayed bright returns in the Escalante Desert of South Central Utah that had scattered cover of greasewood plants, which average 60–90 cm in height. Aeolian sand sheets and present-day playa surfaces appeared nearly black (smooth). In this case the vegetation, not visible on L-band (23.5 cm) radar images, provided a rough surface to the shorter wavelengths and a smooth surface to the longest wavelength radar.

This prompts the question whether differential penetration of vegetative canopies could provide useful information about both the vegetation and the terrain underneath the canopy. Another Willow Run Laboratories/ERIM experiment by Ben Drake in the early 1970s involved his placing corner reflectors on the ground in a deciduous forest in Michigan during the height of the growing season. When this was overflown by an X-band and L-band radar systems (simultaneous data collection), he examined separate images of both radar systems and could not detect the corner reflectors at either wavelength.

However, 2 years after Drake's experiment, Phil Jackson and coworkers created a spectral ratio image (really a ratio gray map produced with symbols on computer paper instead of on film) of X-band to L-band images from the same airborne radar system for a forested region (deciduous) in southeastern Kentucky (near Middlesboro) that showed evidence of canopy penetration by radar. [Figure 3\(a\)](#) and [3\(b\)](#) shows X-band and L-band images, respectively, of a larger region around the immediate study area. [Figure 3\(c\)](#) shows gray maps of the L-band, X-band, and a spectral ratio image of the two radar bands (L/X) for the immediate study area inside the dashed box in the two images in [Figure 3\(a\)](#) and [3\(b\)](#). The arcuate feature designated by 1's in the L-band and X-band images of [Figure 3\(c\)](#) is a 'bench,' or reclaimed area where coal mining has occurred on the steep hillside. It has a rough texture, with shale fragments ranging in size from 3 to 60 cm (though the majority of fragments were in the 3–15 cm range) and covered by grass. The dark 'bench' designated by 2 in the L-band and X-band images of [Figure 3\(c\)](#) (but bright in the L/X ratio image, like the surrounding terrain) was not level, but consisted of several slopes (less than 51°) parallel to the radar look direction. A flat field with rock fragments in approximately the 3–15 cm size range and covered by grass is designated with a 3 in the L-band and X-band images of [Figure 3\(c\)](#). Note that this flat area is brighter in the X-band image than in the L-band image, which is consistent with the theory that surfaces with roughness equal to or greater than half a wavelength appear rough (bright

return in the X-band image) and surfaces with roughness less than half a wavelength appear smooth (dark return in the L-band image). Above the '3' is a small, cross-like bright return on the L-band image that is not discernible on the X-band image. This was a bog with mud and some standing water, with a sparse stand of high weeds of 90–120 cm height. In the spectral ratio, gray map is an arcuate feature designated with a 4 that was found to be an elongated, elliptical depression. This is a real feature on the ground that was hidden in the radar shadow of the L-band and X-band images of [Figure 3\(c\)](#). The ratio image more clearly portrays the topographic information in the presence of apparent shadowing and slope factors, which cause the individual radar signals to vary greatly. The light-toned linear feature above the '5' in the spectral ratio image is an old prospecting cut near the top of the tree-covered mountain. It is a cut about 2 m wide, with a wall approximately 1.0–1.3 m high. The cut at the time of radar data collection was covered completely by trees that were not as mature as those on either side of it but were sufficiently mature not to have been visibly different from their surroundings in an aerial photograph of the area. It appeared to be seen that a ground feature in the spectral ratio image is hidden by trees in the two single-band SAR images of [Figure 3\(c\)](#).

These two experiments bring an important remote sensing dictum to the fore: linear and nonlinear image processing of coregistered spectral bands yields much more information than examination of images of the separate bands can yield. The reasons for this lie in the complexity of reflections of electromagnetic radiation from the surface and from the volume of the medium forming the interface with the air through which the radiation has propagated. There is usually both a surface specular component and a volume component to the reflected radiation. Because first surface reflectance is usually much less dependent on wavelength than the volume reflectance, the spectral ratioing of two bands of radar data tends to suppress the surface reflectance, thereby enhancing the wavelength dependence of the volume reflectance. The surface reflectance is often higher than the volume reflectance, which makes it dominate a single-band image. The ratio image, however, enhances the volume reflectance. What information is embedded in this volume reflectance for forested terrain? There are many layers of information: the total thickness and water content of leaves on the trees, the sizes of twigs and branches on the trees, the thickness of fallen leaves on the ground, and the soil moisture and roughness of the soil underneath the leaves. In the spectral ratio example above, it was either the different limb sizes of the different aged trees or reflections from the rocky ground underneath the trees that was permitted to observe the prospector's cut on the hill.

In seasonal wetlands covered by deciduous forests, it may be possible to use multifrequency radar to determine how far the water table lies beneath the fallen leaves on the forest floor. Generally speaking, however, the complexity of forest canopies creates a need for multifrequency radar. With the great variety of scatterers in forested terrain, more wavelengths (spectral bands) of radar data are required from which to separate the effects of those scatterers on backscattered microwaves.

The effect of an object's shape on radar backscatter is most pronounced when radar waves of like and crossed polarizations are employed for imaging (which is called

Figure 3 Synthetic aperture radar (SAR) data for southeastern Kentucky, near Middleboro. (a) X-band parallel polarization (HH); (b) L-band parallel polarization (HH); and (c) L-band (HH) image, X-band (HH) image, and L(HH)/X(HH) spectral ratio image from left to right, respectively, for the study area shown inside the dashed boxes in images (a) and (b). Reproduced from Jackson, P., Vincent, R.K., Willock, L., et al., 1975. Remote Sensing of Strip Mines – Final Report, ERIM Report No. 108500-14-F to the US Dept of Interior-Bureau of Mines (Grant No. S0241056), Environmental Research Institute of Michigan, PO Box 618, Ann Arbor, Michigan, pp. 34–40.

multipolarization radar) for whatever wavelength of microwave radiation to which it is applied. For instance, Ulaby found that sending and receiving vertically polarized radar waves (called VV for 'vertically filtered source and vertically filtered receiver') provided better classification of agricultural crops (corn in particular) than HH (horizontally filtered source and receiver), or cross-polarized (VH or HV) configurations. The vertical stalks of corn backscatter more vertically polarized radar waves than wave of other polarization orientations, and the radar waves stay vertically polarized on the way back to the detector. Because there are other types of crops that also have vertical stalks (such as sugarcane), multipolarization is an important capability for SAR systems that are intended to map agricultural crops. However, there are many other uses of multipolarized SAR data, which apply whenever the observed object has a preferred shape orientation. One example that has been reported in the literature is the detection of power line cables with VV polarization at angles away from normal incidence, when the backscatter was found to be proportional to the number and diameter of the strands on the surface of the cables. This is an important safety issue for low-altitude airplanes. Another example of multipolarization radar application (also multifrequency radar) is for the mapping of snow depth, liquid water content, and ice crystal size. Radar backscatter at 35 and 95 GHz frequencies, with every possible polarization combination of source and receiver, was experimentally measured and a numerical model was developed and adapted to fit the observations of snow-covered ground.

Forestry applications have already been shown to benefit greatly from multifrequency, multipolarization radar. Dobson and colleagues employed C-band, L-band, and P-band SAR data to study maritime pine plantations near Landes, France and near Duke, NC, USA. They found that they could determine the biomass of the coniferous forests, until the biomass saturated at a biomass level that depends on the radar frequency, ranging from 1001 ha⁻¹ at L-band wavelength to 2001 ha⁻¹ at P-band wavelength. The C-band radar was relatively insensitive to aboveground biomass, probably because of its lesser ability to penetrate the surface of the canopy, compared to the longer wavelength radars. Dobson then showed that X-band and C-band radars employed together were most effective for determining the crown biomass of a forest in northern Michigan. These two wavelengths, combined with L-band SAR, made it possible to determine tree height (0–23 m with 2.4 m RMS error), basal area (0–72 m² ha⁻¹ with 3.5 m² ha⁻¹ RMS error), dry trunk biomass (0–19 kg m⁻² with 1.1 kg m⁻² RMS error), dry crown biomass (0–6 kg m⁻² with 0.5 kg m⁻² RMS error), and total aboveground biomass (0–25 kg m⁻² with 1.4 kg m⁻² RMS error).

Summary and Conclusions

Past applications of multifrequency and/or multipolarization radar have included mapping of geological features, forests, agricultural crops, electric power lines, and snow cover. From experience of these applications, there appears to be additional future applications and general conclusions about multifrequency, multipolarization radar systems:

1. Although multifrequency radar offers no advantage for soil moisture estimations from SAR measurements, it could be used at low incidence angles to determine relative surface roughness, regardless of soil moisture.
2. Multifrequency radar may be able to determine the observation depth of a soil, through the oscillatory nature of the backscatter coefficient as a function of frequency.
3. Generally speaking, the complexity of forest canopies and agricultural crops creates a need for multifrequency, multipolarization radar, because the great variety of scatterers in forested terrain and agricultural fields require more wavelengths (spectral bands) and polarizations of radar data from which to separate the effects of those scatterers on backscattered microwaves.
4. Linear and nonlinear image processing of coregistered spectral bands yields much more information than examination of images of the separate bands can yield.

Radar systems, even with multifrequency, multipolarization capabilities, do not have to be used to the exclusion of data from other wavelength regions. As Ulaby has pointed out, the combination of multifrequency/multipolarization satellite radar data with LANDSAT visible/reflective infrared and thermal infrared data will lead to more accurate crop classifications from space. Not only do they provide better classifications when employed together but radar data can also penetrate clouds, thereby providing critical information during the growing season, even when clouds obscure the ground for shorter wavelengths of electromagnetic radiation. A multifrequency, multipolarization radar satellite in an orbit offset from and synchronous with a LANDSAT TM orbit would provide data from the visible, reflective infrared, thermal infrared, and microwave wavelength regions, collected simultaneously. The ability to map chemical composition variations on the ground while simultaneously mapping soil moisture would permit users to map trafficability for providing advice to farmers about the best times for farm machinery to be taken into the field without getting stuck, as well as for many other trafficability applications. Agriculture, forestry, geology, snow cover, power line, and trafficability mapping would all benefit from such a system.

PREFACE TO THE FIRST EDITION

A half century ago the American Meteorological Society published the *Compendium of Meteorology*, which in a single volume of 1334 pages summarized the state of understanding of the atmosphere at that time. A perusal of the contents of that volume indicates that although a broad range of topics was covered, the vast bulk of the volume was devoted to traditional meteorological topics such as atmospheric dynamics, cloud physics, and weather forecasting. Barely 4 percent of the volume was devoted to articles related to atmospheric chemistry or air pollution and, of course, none of the volume was devoted to techniques such as satellites and remote sensing.

As Sir John Mason aptly notes in his foreword to the present work, the atmospheric sciences have expanded in scope enormously over the past 50 years. Topics such as atmospheric chemistry and global climate change, of only marginal interest 50 years ago, are now central disciplines within the atmospheric sciences. Increasingly, developing areas within the atmospheric sciences require students, teachers, and researchers to familiarize themselves with areas far outside their own specialties. This work is intended to satisfy the need for a convenient and accessible references source covering all aspects of atmospheric sciences. It is written at a level that allows undergraduate science and engineering students to understand the material, while providing active researchers with the latest information in the field.

More than 400 scientists, from academia, government, and industry have contributed to the 330 articles in this work. We are very grateful to these authors for their success in providing concise and authoritative summaries of complex subjects. As editors, we have benefited from the chance to learn from these articles, and we believe that all students and active scientists who want to increase their knowledge of the atmosphere will benefit enormously from access to this work.

We are also grateful to the 31 members of the Editorial Advisory Board who have guided us in our coverage of the very broad range of topics represented in this encyclopedia. Their willingness to suggest topics and authors, and to carefully review draft articles has contributed significantly to our success.

The production of this multivolume encyclopedia would not have been possible without the dedicated work of the staff of the Major Reference Works group at Academic Press. We are especially grateful to the Major Reference Work Development Manager, Colin McNeil, who has worked closely with us during the entire process. Finally, we appreciate the liberal use of color figures in the printed encyclopedia.

James R Holton, Judith A Curry, and John Pyle

PREFACE TO THE SECOND EDITION

Since the publication of the first edition of the *Encyclopedia of Atmospheric Sciences*, significant advances in research have been achieved all across the broad and expanding spectrum of the field and related disciplines. In particular, climate science with primary input from the atmospheric research emerges as a new field and integrator of interlocking peripheral disciplines over the last decade. These events have demanded the solicitation of new and updated articles for the 2003 edition. Some articles from the earlier publication were judged to be of such a fundamental and enduring nature that they did not require modification. But huge amounts of new information from Earth-orbiting satellite observatories have brought much new insight to the field. In addition there are new findings in many areas such as the latest simulations of meteorological and climatic processes of interest as well as simulations and observations of the composition and interaction of the field's chemical constituents. While interest in the ozone hole and its ramifications may have reached a plateau, ever more understanding of the stratosphere and its role in climate change emerges. The study of past climates provides new means of testing climate models and theories. In weather prediction we see new progress on how data are to be better assimilated for much improved initialization of the forecast model leading to the promise of more accurate predictions of severe weather and tropical cyclones over longer lead times. These are just a few of the new features of the second edition.

The editors of the second edition are greatly indebted to our predecessors in the first edition. They set the outline of topics and solicited the original authors, while establishing a high standard for the content of this publication. In many cases we decided to reprint those articles or request only minor updates. Nevertheless, many articles in this edition are entirely original, based on which we also made significant reorganization of the content. We are proud of our product and hope it provides the same assistance to students, researchers, and practitioners throughout the science and engineering communities.

Editors of the second edition
Gerald R North
Fuqing Zhang
John Pyle

EDITOR BIOGRAPHIES

Gerald R North received his PhD in theoretical physics from the University of Wisconsin in 1966. After postdoctoral research at the University of Pennsylvania he became a faculty member in physics at the University of Missouri—St. Louis. He shifted his research focus to climate science research during his sabbatical year at the National Center for Atmospheric Research, where he won the Outstanding Paper Award in 1975. He moved to NASA Goddard Space Flight Center (GSFC) in 1978 where he was awarded the NASA Medal for Research Excellence. During his stay at GSFC, he was the proposer and first study scientist for the Tropical Rainfall Measuring Mission, which was launched in 1997 and is still orbiting in 2014.

He moved to Texas A&M University in 1986 as a university distinguished professor of atmospheric sciences where he served as department head from 1995 to 2003. He has served as editor-in-chief of the *Reviews of Geophysics* and is recognized as one of the most cited authors in geosciences (Web of Science). He has chaired and/or served on a number of national committees and is a Fellow of the American Geophysical Union, American Meteorological Society (AMS) and the American Association for the Advancement of Science, and winner of the Jule Charney Award for Research (AMS).

He has published about 150 refereed papers not including many book chapters and reviews. His books include *Paleoclimatology*, co-authored with Thomas Crowley, and *An Introduction to Atmospheric Thermodynamics* co-authored with Tatiana Erikhimova.

North's interests are focused on the use of mathematical and statistical tools to solve climate problems over a wide range of issues including: analytical solutions of simplified energy balance climate models, use of random field techniques in representing and interpreting climate data and model simulations, detection of deterministic signals in climate change, statistical analysis satellite remote sensing for mission planning and analysis of data, paleoclimate problems using simplified climate models.

John Pyle obtained a BSc in Physics at Durham University before moving to Oxford where he completed a DPhil in Atmospheric Physics, helping to develop a numerical model for stratospheric ozone studies. After a short period at the Rutherford Appleton Laboratory he moved to a lectureship at Cambridge University in 1985. In 2000 he was appointed professor of atmospheric science and since 2007 has been the 1920 professor of physical chemistry. He is a Professorial Fellow at St Catharine's College. He has been a codirector of Natural Environment Research Council's National Centre for Atmospheric Science, where he is currently Chief Scientist.

His research focuses on the numerical modelling of atmospheric chemistry. Problems involving the interaction between chemistry and climate have been addressed; these range from stratospheric ozone depletion to the changing tropospheric oxidizing capacity and have included the environmental impact of aviation, land use change, biofuel technologies, and the hydrogen economy. He has studied palaeochemistry problems as well as the projected atmospheric composition changes during the current century. He has published more than 250 peer reviewed papers.

He played a major role in building an EU stratospheric research programme in the 1990s, coordinating several major field campaigns. He has contributed to all the WMO/UNEP assessments on stratospheric ozone since the early 1980s and is now one of the four international cochairns on

the Scientific Assessment Panel, responsible for these assessments. He was a convening lead author in the IPCC Special report "Safeguarding the ozone layer and the global climate system," published in 2006.

He was elected Fellow of the Royal Society in 2004 and an American Geophysical Union Fellow in 2011. He was awarded the Cambridge ScD degree in 2012. Other honours and awards include membership of Academia Europaea (1993), Royal Society of Chemistry (Interdisciplinary award, 1991, and John Jeyes lectureship, 2008), and the Royal Meteorological Society Adrian Gill Prize, in 2004.

Fuqing Zhang is a professor with tenure in the Department of Meteorology at the Pennsylvania State University, with a joint appointment in the Department of Statistics, along with an endowed position as the E Willard & Ruby S Miller Faculty Fellow at the College of Earth and Mineral Sciences at the Pennsylvania State University. His research interests include atmospheric dynamics and predictability, data assimilation, ensemble forecasting, tropical cyclones, gravity waves, mountain plains and sea-breeze circulations, warm-season convection, and regional-scale climate. He earned his BS and MS in meteorology from Nanjing University, China in 1991 and 1994, respectively, and his PhD in atmospheric science in 2000 from North Carolina State University.

He spent seven years as an assistant and then associate professor at Texas A&M University before coming to Penn State University as a full professor in 2008. In 2000, he spent a year and a half as a postdoctoral fellow at the National Center for Atmospheric Research. He also held various visiting scholarship appointments at various academic and research institutions including the National

Center for Atmospheric Research in Boulder, Colorado; the Navy Research Laboratory in Monterey, California; NOAA/AOML Hurricane Research Division, Miami, Florida; Peking University and Nanjing University, China; the Chinese State Key Laboratory of Severe Weather in Beijing, China; and Laboratoire de Meteorologie Dynamique, École Normale Supérieure in Paris, France.

He has authored/co-authored about 130 peer reviewed journal publications and has given more than 160 keynote speeches or invited talks at various institutions and meetings. He has served as principal investigator/co-principal investigator for 30 federal or state-sponsored research grants. He has chaired/cochaired more than 10 scientific meetings or workshops. He also served on various review or advisory panels for numerous organizations that include National Science Foundation, Office of Naval Research, NASA, NOAA, and National Academies. He has also served as editor of several professional journals including *Monthly Weather Review*, *Science China*, *Atmospheric Science Letter*, *Acta Meteorologica Sinica*, and *Computing in Science & Engineering*.

He has also received numerous awards for his research and service. Notably, in 2007 he received the **Outstanding Publication Award** from the National Center for Atmospheric Research. In 2009, was the sole recipient of the American Meteorological Society's 2009 **Clarence Leroy Meisinger Award** "for outstanding contributions to mesoscale dynamics, predictability, and ensemble data assimilation." Most recently, he received the 2014 American Meteorological Society's **Banner Miller Award** "for valuable insights into incorporating real-time airborne Doppler radar measurements via ensemble data assimilation, leading to improvements in forecasts of tropical cyclone track and intensity."

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is not arranged by ordinary alphabetical order, but by alphabetical order according to 49 principal topic areas taken to allow all papers belonging to each principal topic to appear together in the same volume. Within each principal subject, article headings are also arranged alphabetically, except where logic dictates otherwise. For example, overview articles appear at the beginning of a section.

There are four features that help you find the topic in which you are interested:

- i. the contents list
- ii. cross-references to other relevant articles within each article
- iii. a full subject index
- iv. contributors

i. Contents List

The contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

ii. Cross-references

All of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an article as a See also list, serve four different functions:

- i. To draw the reader's attention to related material in other entries

- ii. To indicate material that broadens and extends the scope of the article
- iii. To indicate material that covers a topic in more depth
- iv. To direct readers to other articles by the same author(s)

Example

The following list of cross-references appears at the end of the article.

Synopsis

Almost all known physical and biological cycles in the Earth's system are driven by the electromagnetic radiation emitted by the Sun, known as solar radiation. Solar radiation is also the major cause of climate change that is truly from outside the Earth's system.

Introduction

The Sun as an average star is a typical main-sequence dwarf of spectral class G-2. Its radius is 6.960×10^8 m. The mean distance between the Sun and the Earth is 1.496×10^{11} m and is known as the astronomical unit. Solar radiation is the electromagnetic radiation emitted by the Sun. Almost all known physical and biological cycles in the Earth system are driven by the solar radiation reaching the Earth. Solar radiation is also the cause of climate change that is truly exterior to the Earth system.

Solar Spectrum and Total Solar Irradiance

The distribution of solar radiation as a function of the wavelength is called the solar spectrum, which consists of a continuous emission with some superimposed line structures. The Sun's total radiation output is approximately equivalent to that of a blackbody at 5770 K. The solar radiation in the visible and infrared spectrum fits closely with the blackbody emission at this temperature. However, the ultraviolet (UV) region ($<0.4 \mu\text{m}$) of solar radiation deviates greatly from the visible and infrared regions in terms of the equivalent blackbody temperature of the Sun. In the interval $0.1\text{--}0.4 \mu\text{m}$, the equivalent blackbody temperature of the Sun is generally less than 5770 K with a minimum of about 4500 K at about $0.16 \mu\text{m}$. The deviations seen in the solar spectrum are a result

of emission from the nonisothermal solar atmosphere. Of the radiant energy emitted from the Sun, approximately 50% lies in the infrared region ($>0.7 \mu\text{m}$), about 40% in the visible region ($0.4\text{--}0.7 \mu\text{m}$), and about 10% in the UV region ($<0.4 \mu\text{m}$).

The total solar irradiance (TSI) is the amount of solar radiation received outside the Earth's atmosphere on a surface normal to the incident radiation per unit time and per unit area at the Earth's mean distance from the Sun. The TSI is an important value for the studies of global energy balance and climate. Direct measurements of TSI can be made only from space, and more than 30-year record has been obtained based on overlapping satellite observations. The most accurate value of TSI during the solar minimum period is $1360.8 \pm 0.5 \text{ W m}^{-2}$ according to measurements from the Total Irradiance Monitor on NASA's Solar Radiation and Climate Experiment and a series of new radiometric laboratory tests.

The TSI is not in fact perfectly constant, but varies in relation to the solar activities. Beyond the very slow evolution of the Sun, a well-known solar activity is the sunspots, which are relatively dark regions on the surface of the Sun. When solar activity is high as indicated by the number of sunspots, the TSI increases. The periodic change in the number of sunspots is referred to as the sunspot cycle, and takes about 11 years, the so-called 11-year cycle. The cycle of sunspot maxima having the same magnetic polarity is referred to as the 22-year cycle. The Sun also rotates on its axis once in about 27 days. Satellite observations suggest that TSI values increase by approximately 0.12%

(1.6 W m^{-2}) between solar minimum and maximum. Such change might be too small to directly cause more than barely detectable changes in the tropospheric climate: empirical analysis indicates a global surface temperature increase of $\sim 0.1 \text{ K}$ as the TSI increases from the minimum to maximum of recent solar activity cycles. However, some indirect evidence indicates that the changes of TSI related to sunspot activity may have been significantly larger over the last several centuries. Furthermore, solar variability is much larger (in relative terms) in the UV region, and induces considerable changes in the chemical composition, temperature, and circulation of the stratosphere, as well as in the higher reaches of the upper atmosphere.

Distribution of Solar Insolation at the Top of the Atmosphere

The solar insolation is the actual amount of solar radiation incident upon a unit horizontal surface over a specified time for a given locality. It depends strongly on the solar zenith angle θ_0 and also on the ratio (d/d_m) of the actual distance to the mean distance of the Earth from the Sun. The solar irradiance at the top of the atmosphere may be expressed by

$$F = S(d_m/d)^2 \cos \theta_0 \quad [1]$$

where S is the TSI. The solar zenith angle depends on the latitude, day of year, and time of day, and is given by

$$\cos \theta_0 = \sin \lambda \sin \delta + \cos \lambda \cos \delta \cos h \quad [2]$$

where λ is the latitude, δ the solar declination, and h the hour angle. The hour angle is 0 at solar noon and increases by 15° for every hour away from solar noon. The solar zenith angle is 90° at sunset and sunrise. Then the solar insolation for a specified period of time between t_1 and t_2 is given by

$$Q = \int_{t_1}^{t_2} F(t) dt. \quad [3]$$

The daily insolation at the top of the atmosphere can be determined by integration of eqn [3] over a day. For a given day of the year, the solar declination and the ratio d/d_m can be determined from standard astronomical formulas. Under present astronomical conditions, the solar declination varies from $23^\circ 27'$ on 21 June to $-23^\circ 27'$ on 22 December, while $(d_m/d)^2$ ranges from 1.034 3 on 3 January to 0.967 4 on 5 July. The values of the daily insolation at the top of the atmosphere are presented in Figure 1 as a function of latitude and time of year.

It is clear that the distribution of solar insolation at the top of the atmosphere depends on the Earth's elliptical orbit around

Figure 1 Daily solar insolation at the top of the atmosphere as a function of latitude and day of year. The shaded areas denote zero insolation. The positions of vernal equinox (VE), summer solstice (SS), autumnal equinox (AE), and winter solstice (WS) are indicated with solid vertical lines. Solar declination is shown with a dashed line. the Sun through δ and d/d_m . Because of the gravitational attraction between the Earth and other planets, the orbital parameters including the eccentricity of the orbit, the tilt of the angle, and the longitude of the perihelion vary with characteristic periods of about 100 000, 41 000, and 21 000 years, respectively. The variations of these orbital parameters of the Earth may constitute a cause for climate changes as those experienced during the Pleistocene ice ages.

Scattering and Absorption of Solar Radiation in the Earth–Atmosphere System

Solar radiation entering the Earth's atmosphere is absorbed and scattered by atmospheric gases, aerosols, clouds, and the Earth's surface. The absorbed radiation is added directly to the heat budget; whereas the scattered radiation is partly returned to space and partly continues its path through the Earth–atmosphere system where it is subject to further scattering and absorption. The fraction of the incident solar radiation that is reflected and backscattered to space is called the albedo. We might speak of the albedo of the entire Earth or of individual surfaces with reference either to monochromatic radiation or to the total incident solar radiation. In this last sense the albedo of the Earth as a whole is about 0.30.

Effects of Atmospheric Gases on Solar Radiation

The scattering of solar radiation by air molecules can be described by a theory developed by Rayleigh who showed that the amount of scattering is inversely proportional to the fourth power of the wavelength, when the sizes of particles are much smaller than the wavelength of the incident radiation. We see blue sky because atmospheric molecules scatter solar radiation much more in the blue than in the red part of the spectrum. In fact, the sky is made visible through the scattering process. On the other hand, sunsets and sunrises appear reddish because the blue light in the direct light is removed by scattering during the long path through the atmosphere, leaving the remaining reddish colors of the spectrum.

Atmospheric gases also absorb solar radiation in selected wavelength bands. The UV radiation with wavelengths shorter than $0.3 \mu\text{m}$ is lethal to the biosphere. The UV radiation in the interval $0.2\text{--}0.3 \mu\text{m}$ is mainly absorbed by O_3 in the stratosphere. The small amount of radiation with wavelengths shorter than $0.2 \mu\text{m}$ is absorbed at higher levels by O_2 , N_2 , O , and N . The photochemical processes due to absorption of solar UV radiation involving various forms of oxygen are critical in determining the amount of ozone in the stratosphere. The absorption spectrum of O_2 between 0.2 and $0.26 \mu\text{m}$ is weak but of significance in the formation of ozone.

In the troposphere, the absorption of solar radiation occurs in the visible and near infrared regions, owing primarily to H_2O , CO_2 , O_2 , and O_3 . The absorption in the visible, however, is very weak. Figure 2 shows the depletion of solar radiation in a clear atmosphere. The top curve is the solar spectrum at the top of the Earth's atmosphere and the lower curve represents the spectrum at the sea level; the shaded area gives the combined effects of scattering and absorption of solar radiation

Figure 2 Solar spectrum at the top of the atmosphere and at the surface for a solar zenith angle of 60° in a clear atmosphere. Absorption and scattering regions are indicated. Adapted with permission from Liou, K.N., 2002. *An Introduction to Atmospheric Radiation*. Academic Press, San Diego, CA.

by atmospheric gases. It is evident that the depletion of solar radiation is dominated by ozone absorption in the UV, Rayleigh scattering in both UV and visible, and water vapor absorption in the near infrared regions.

Effects of Aerosols on Solar Radiation

Aerosols are suspensions of liquid and solid particles in the atmosphere, excluding clouds and precipitation. The aerosol particle sizes range from 10^{-4} to $10 \mu\text{m}$, falling under the following broad categories: sulfates, black carbon, organic carbon, dust, and sea salt. Aerosol concentrations and compositions vary significantly with time and location. Visibility measurements reflect the aerosol concentration at ground level. The visual range can vary from a few meters to 200 km, depending on the proximity to sources, the strength of the sources, and atmospheric conditions.

Aerosols scatter and absorb solar radiation. Sulfate aerosols scatter primarily solar radiation and cause cooling of the Earth–atmosphere system. The increase in the reflected solar radiation at the top of the atmosphere due to such nonabsorbing aerosols is nearly identical to the reduction in the solar radiation at the surface. Carbonaceous aerosols (black carbon and organics) absorb and scatter solar radiation. The presence of black carbon aerosols results in the absorption of solar radiation, which reduces the solar radiation reaching the surface. At the same time, these aerosols absorb the upward solar radiation reflected from below and reduce the solar radiation reflected to space. Therefore, the effect of black carbon aerosols opposes the cooling effect of other aerosols at the top of the atmosphere, whereas at the surface all aerosols reduce the solar radiation. The changes arising from the aerosol scattering

and absorption of solar radiation are referred to as their direct radiative forcing. Aerosols can also modify the solar radiation through their role in cloud condensation and as ice nuclei, an effect known as aerosol indirect radiative forcing.

Aerosol particles in the atmosphere are produced both in nature and by people. A global aerosol optical depth of about 0.12 is suggested. These aerosols increase the reflected solar radiation at the top of the atmosphere by about 3 W m^{-2} globally. Anthropogenic sources contribute significantly to the global aerosol optical depth. Global anthropogenic emissions of sulfates, organics, and black carbon even exceed natural sources. Such a large perturbation of the global aerosol loading due to human activities may significantly modify regional and global climates.

Effects of Clouds on Solar Radiation

Clouds regularly cover about 65% of the Earth, and occur in various types. Some, such as cirrus in the tropics and stratus near the coastal areas and in the Arctic are climatologically persistent. Like aerosols, clouds show substantial spatial and temporal variations.

Clouds are the most important regulator of solar radiation. By reflecting incoming solar radiation back to space, they cool the Earth–atmosphere system – the so-called cloud albedo effect. Clouds also absorb solar radiation in the near infrared region. The cooling of the Earth–atmosphere system due to the cloud albedo effect occurs primarily at the surface. The solar albedo of clouds depends substantially on cloud type and cloud form, as well as the solar zenith angle.

The most straightforward and simple diagnostic measure of the impact of clouds on solar radiation is the short-wave cloud forcing which is defined as the difference of the net solar irradiances at the top of the atmosphere between all-sky and cloudless conditions. Here the net irradiance is the incoming solar radiation minus the reflected radiation. Satellite measurements suggest that the global short-wave cloud forcing is about -45 W m^{-2} . Short-wave cloud forcings are maximized (about -120 W m^{-2}) in the summer hemisphere at about latitude 60° where solar input is large and low clouds are abundant, with a secondary maximum in tropics. Note that the magnitude of short-wave cloud forcing is about 10 times as large as those for a CO_2 doubling. Hence small changes in the cloud-radiative forcing fields can play a significant role as a climate feedback mechanism.

Solar Radiation at the Earth's Surface

The radiation coming directly from the Sun received at the Earth's surface is called direct solar radiation. The amount of scattered radiation coming from all other directions is called diffuse solar radiation. The sum of both components as received on a horizontal surface is called global solar radiation.

A significant fraction of the incoming solar radiation is reflected back by the surface. The surface albedo, defined as the ratio of the reflected over the incoming radiation, depends on the nature of the surface, solar zenith angle, and wavelength. For a water surface the albedo is about 0.06, whereas for snow the albedo is about 0.6–0.8. The albedo of bare sea ice is about 0.4. Since large areas of Earth are covered by water, snow, and sea ice, changes in the snow and sea ice cover can have a significant impact on the global albedo.

Bare land surfaces have typical surface albedo of 0.1–0.35, with the highest value for the desert sand. Albedos of most vegetation surfaces fall in the range of 0.1–0.25. The albedo for green vegetation depends greatly on wavelengths, reflecting strongly in the near infrared but absorb in the ultraviolet and visible regions.

Annual Global Mean Energy Budget of Solar Radiation

The energy budget of solar radiation can be derived by combining observations and modeling studies, which shows combined effects of atmospheric gases, aerosols, clouds, and surfaces. Under the annual global mean condition, the incident solar radiation at the top of the atmosphere is 340 W m^{-2} . Of this incident solar radiation, 75 W m^{-2} is absorbed during passage through the atmosphere. A total of 100 W m^{-2} is reflected back to space: 23 W m^{-2} from the surface and 77 W m^{-2} from clouds and aerosols and atmosphere. The remaining 165 W m^{-2} are absorbed at the Earth's surface. It is noted that while the incoming and reflected solar irradiances at the top of the atmosphere are constrained by satellite observations, uncertainties may exist for the partitioning of the absorbed solar radiation between the atmosphere and the surface on the global scale.

Synopsis

This article covers the physical processes responsible for solar and thermal radiation as well as the physical laws governing such processes, properties of gaseous absorptions, common algorithms used to solve the radiative transfer in the absence of scattering, radiative properties of the Earth's atmosphere, and general thermodynamics in the context of the radiation field.

Solar and Thermal Radiation

In the final analysis, all physical or biological processes that take place on Earth owe their existence to the absorption of radiation from the Sun. In the absence of this radiation, the Earth would be cold and lifeless, at a temperature close to that of the cosmos, 2.73 K.

Solar radiation corresponds approximately to a blackbody emission temperature of 5780 K. Solar radiation reaching the Earth is, in part, scattered back to space. The remainder is absorbed and heats the Earth, which, in turn, emits thermal radiation to space. A long-term balance between absorption and emission leads to an average terrestrial emission temperature of approximately 255 K (substantially less than the observed surface temperature).

Internally to the atmosphere, thermal radiation is emitted and absorbed, transporting energy from warmer levels to colder levels. Consequently, the radiation field is characterized by the radiance, $I_{\nu,\lambda}(l)$, defined as the rate of flow of energy in the l -direction, for a unit area perpendicular to l , for a unit solid angle, and for a unit range of frequency or wavelength (ν or λ). The units are $\text{W m}^{-2} \text{sr}^{-1} (\nu \text{ or } \lambda)^{-1}$, where sr stands for steradian.

The Interaction Process

The interaction between a photon and an air molecule can be described in varying degrees of complexity, but a simplified picture of a one-stage process conveys the general nature of absorption and scattering (see Figure 1).

Figure 1 A molecule–photon interaction. The branching depends on the ratio of the collisional thermalization rate to the spontaneous decay rate.

The molecule is assumed to exist in one of two quantized states, M and M^* . M represents the state before interaction with the photon ($h\nu$). We will assume that this initial state is in thermodynamic equilibrium (i.e., the populations of energy levels are determined by Boltzmann's law). The first stage in the interaction is for the photon to disappear and the molecule to be raised to the excited state, M^* (which will not be in Boltzmann equilibrium).

In the second stage of the interaction, several things may happen to the excited molecule, M^* , including decomposition and chemical reactions. Leaving chemistry aside, there are two generic possibilities. First, collisions with other molecules may be so rapid that the excess energy in M^* is thermalized and the molecule returns to an equilibrium state, but with slightly more internal energy in the thermal reservoir. This process is absorption.

The alternative process is for the excited molecule to decay spontaneously, as all excited molecules will if left undisturbed for long enough. This again returns the molecule to an equilibrium state, but now a photon is emitted that is the same as the incident photon, except with different direction and different polarization. The internal energy of the thermal reservoir is unchanged. This is a coherent scattering process. The branching between absorption and scattering depends upon the ratio of the times for collisional thermalization and spontaneous decay. For all bands that will be discussed in the section Gaseous Absorption, this ratio is very small in the troposphere and stratosphere, and absorption is the dominant mode of interaction between molecules and radiation in the lower atmosphere.

The absorption coefficient per molecule, $k_{\nu,\lambda}$, is defined with respect to those photons that disappear in the interaction process (i.e., are absorbed). It is the cross-section for an absorbing collision between a photon and a molecule, and its units are square meters (m^2). Experimentally, it is the fractional change in radiance for radiation traversing an absorption tube in which it interacts with one molecule per unit area of tube cross-section (eqn [1]).

$$dI_{\nu,\lambda} = -nk_{\nu,\lambda}I_{\nu,\lambda}ds = +I_{\nu,\lambda}d\tau_{\nu,\lambda} \quad [1]$$

Here, n is the molecular number density, ds is the infinitesimal absorbing path, and $\tau_{\nu,\lambda}(= \int_{\text{path}} nk_{\nu,\lambda}ds)$ is the optical path. Note that, by convention, the direction of the path is always defined in such a way that $dI_{\nu,\lambda} = -nk_{\nu,\lambda}I_{\nu,\lambda}ds$.

Although the internal energy must be described differently, an analogous situation and analogous definitions exist when a single molecule is replaced by a single aerosol particle.

Again, both scattering and absorption can take place, although the branching is not controlled by the molecular collision rate. In this article, discussion will be limited to gaseous absorption (particle and droplet scattering are treated elsewhere; *see Aerosols: Role in Radiative Transfer*; and *Radiation Transfer in the Atmosphere: Scattering*).

Thermal Emission

Thermal emission is the complementary process to absorption: internal energy is transferred spontaneously from the thermal reservoir to photons in the radiation field. In Boltzmann equilibrium, states above the ground state have finite populations and there is a probability that decay by spontaneous emission will take place, emitting a photon. As a consequence, there is a steady state of photons associated with the interior of a constant-temperature enclosure or cavity. Cavity or black-body radiation is, according to Kirchhoff's laws, isotropic and the same as that emitted by a perfectly black body at the same temperature; the radiance is designated $B_\lambda(T)$, where T is the absolute temperature.

All meteorological and climatological studies assume that air molecules are in a state of local thermodynamic equilibrium, whereby Boltzmann equilibrium is obeyed on a local basis. Consequently, equilibrium radiation laws can be employed. But this may not be correct at low pressures, when collisions are infrequent. In the upper atmosphere, a nonequilibrium approach to radiation and fluid mechanics is necessary.

$B_\lambda(T)$ is governed by Kirchhoff's and Planck's laws. It can be expressed as a function of its maximum value (eqn [2]) and the dimensionless number $x = hc/k_B\lambda T$, where h , k_B , and c are, respectively, Planck's constant, Boltzmann's constant, and the speed of light.

$$\frac{B_\lambda}{B_\lambda(\max)} = 4.717 \times 10^{-2} \frac{x^5}{e^x - 1} \quad [2]$$

$B_\lambda(\max)$ is given by eqn [3]:

$$B_\lambda(\max) = 4.1069 \times 10^{-6} T^5 \text{ W m}^{-3} \text{ sr}^{-1} \quad [3]$$

The wavelength of the maximum emission is given by Wien's displacement law (eqn [4]).

$$\lambda(\max) = 2.8978 \times 10^{-3} T^{-1} \text{ m} \quad [4]$$

For $T = 5780 \text{ K}$, the maximum emission is at $0.501 \mu\text{m}$, in the center of the visible spectrum; for $T = 255 \text{ K}$, the maximum is at $11.36 \mu\text{m}$, in the middle infrared spectrum.

The integral of the radiance over all wavelengths is given by the Stefan-Boltzmann relation (eqn [5]), where σ is the Stefan-Boltzmann constant, equal to $5.670 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$.

$$\int_0^\infty B_\lambda(T) d\lambda = B(T) = \frac{\sigma}{\pi} T^4 \quad [5]$$

From Kirchhoff's laws, the radiance emitted from an infinitesimal path ds in thermodynamic equilibrium is given by eqn [6].

$$dI_\lambda = +nk_\lambda B_\lambda(T) ds = -B_\lambda(T) d\tau_\lambda \quad [6]$$

Gaseous Absorption

Bands and Line Spectra

The Earth's atmosphere has a rich absorption spectrum of hundreds of thousands of lines and continuum features extending from the ultraviolet to the microwave spectra, belonging to many different atmospheric gases. Most of the absorptions are vibration-rotation bands, for which the band center is determined by a vibrational transition, with simultaneous rotational transitions forming branches of discrete lines on either side of the center. In the absence of a vibrational transition, lines forming a pure rotation band can exist in the far infrared and microwave spectra. In one case (the oxygen red and infrared bands), an electronic transition is also involved in the infrared spectrum, but usually electronic transitions are to be found in the visible and ultraviolet spectra, and are continua rather than line spectra.

Line and band strengths (S_{line} and S_{band} , which are integrals of the absorption coefficient over a line or band) vary over an enormous range, depending upon the nature of the molecule and the transition. They are proportional to the state population of the lower state involved, which is governed by Boltzmann's law and can be highly temperature dependent.

Figure 2 shows two typical spectral regions at high resolution. Figure 2(a) shows the regular structure of a simple linear molecule. Figure 2(b) shows the more complex structure exhibited by a molecule with three different moments of inertia. Both have been calculated from the HITRAN database (<http://www.cfa.harvard.edu/hitrان/>). HITRAN is a compilation of spectroscopic parameters with relevance to the emission and transmission of light within the atmosphere. The latest version of HITRAN, HITRAN2008, contains information on 2 713 968 spectral lines for 39 different molecules and their associated isotopologues, ranging from the ultraviolet to the microwave spectrum. The data are freely available upon request via the HITRAN website. GEISA (Gestion et Etude des Informations Spectroscopiques Atmospheriques) is a similar database that is more frequently used in Europe; it is also freely available online, via the Center for Atmospheric Chemistry Products and Services hosted at the Institut Pierre Simon Laplace, France (<http://ether.iplsl.jussieu.fr>). The latest version of GEISA, GEISA 2009, lists 3 794 488 lines for 50 molecules (111 isotopic species) in total.

HITRAN data for each line include molecule, line strength, line frequency, molecular parameters for the transition, lower state energy (for Boltzmann calculations), linewidths for air- and self-broadening collisions, temperature dependence of the linewidth, references, and error codes. In general, most lineshape information and data on continua must be supplied from other sources. Figure 3 shows a low spectral resolution composite (i.e., the lines are unresolved) of the atmospheric transmission for bands of the most important atmospheric gases.

Line Profiles

The line profile is the absorption coefficient divided by the line strength (eqn [7]), where ν_0 is the frequency of the line center.

$$f(\nu - \nu_0) = \frac{k_\nu}{S_{\text{line}}} \quad [7]$$

Figure 2 High-resolution spectra. The spectra are calculated from a line-by-line model based on GENLN (general purpose line-by-line atmospheric transmittance and radiance model), using the HITRAN (high-resolution transmission) database. (a) The fundamental vibration–rotation band of N_2O at 1285 cm^{-1} ($1 \text{ cm}^{-1} = 10^4/\lambda(\mu\text{m})$). The absorption path is the atmosphere above 21 km for a zenith angle of 30° . (b) The H_2O rotation band near 670 cm^{-1} . The absorption path is for the entire atmosphere at a zenith angle of 30° . The concentration of water vapor is 3% of a typical terrestrial concentration.

Since lines are formed during close collisions, the theory is extremely complicated, and use is commonly made of empirical corrections to two simple approximations: the Michelson–Lorentz profile and the Doppler profile.

The Michelson–Lorentz profile is an approximation to the line profile of a stationary molecule bombarded by others, with a mean time, t , between collisions. The profile is given by eqn [8], where A is a small line shift parameter and α_L is the Michelson–Lorentz linewidth, given by eqn [9].

$$f_L(\nu - \nu_0) = \frac{\alpha_L}{\pi[(\nu - \nu_0 - A\alpha_L)^2 + \alpha_L^2]} \quad [8]$$

$$\alpha_L = \frac{1}{2\pi t} \quad [9]$$

According to eqn [9], the linewidth is proportional principally to the air density, and therefore to the pressure, hence the term ‘pressure broadening.’

The Doppler profile is appropriate to a collision-free, thermally agitated molecule. The Doppler profile is given by eqn [10], with α_D given by eqn [11] where α_D is the Doppler linewidth and m is the mass of the absorbing molecule.

$$f_D(\nu - \nu_0) = \frac{1}{\pi^{1/2}\alpha_D} \exp\left[-\left(\frac{\nu - \nu_0}{\alpha_D}\right)^2\right] \quad [10]$$

$$\alpha_D = \frac{v_0}{c} \left(\frac{2k_B T}{m} \right) \quad [11]$$

For a water vapor line at 200 cm^{-1} and a temperature of 300 K , the Doppler width is $3.4 \times 10^{-4} \text{ cm}^{-1}$. A typical Michelson–Lorentz width with air as a perturber is 0.05 cm^{-1} at 10^5 Pa . The two widths are approximately equal for a pressure of $\sim 10^3 \text{ Pa}$, which occurs near 30 km altitude in the atmosphere. Below 30 km , Doppler broadening may be neglected; above 30 km , it may be important. A convolution between the two shapes, known as the Voigt profile, is frequently used for taking both broadening mechanisms into account.

Note that the Michelson–Lorentz profile is derived assuming the simplest treatment of collisional broadening. More detailed treatments give complicated profiles, such as the Ben–Reuven (which considers the quantum mechanical treatment of collisional broadening), Van Vleck–Weisskopf, and kinetic lineshapes, the latter two of which are special cases of the Ben–Reuven profiles. The kinetic lineshape is sometimes also known as the Zhevakin–Naumov or Gross lineshape. The discrepancies between such complicated lineshapes and the Michelson–Lorentz profile can be significant in the far wings of absorption lines. Theory and laboratory measurements indicate that the Michelson–Lorentz profile is quite precise for displacements from line centers less than $\sim 2 \text{ cm}^{-1}$. At greater

Figure 3 Vertical transmission of the entire atmosphere for the most important atmospheric absorbers; spectral resolution 10 cm^{-1} . The first panel shows blackbody radiances corresponding to solar and terrestrial temperatures. The scales are such that areas correspond to energies. The two blackbody curves have been normalized to have equal areas. The transmission scales differ from panel to panel and alternate on left and right sides. The third panel shows the water vapor line and continuum transmissions as distinct species.

displacements, important deviations have been measured for water vapor and carbon dioxide lines. These empirical departures from the Michelson–Lorentz profile must be incorporated into radiation algorithms by the user. Given complete line profiles and the data in HITRAN or GEISA, it is possible to calculate the monochromatic absorption coefficient due to lines at any frequency in the terrestrial spectrum.

Continua

The visible and ultraviolet absorptions of O_3 and O_2 are the results of electronic transitions to unquantized upper states, and they show no line structure.

Between 8 and $13\text{ }\mu\text{m}$ is a translucent region in the water vapor spectrum in which the most important absorption is a continuum formed by far wings of very strong lines in the adjacent bands. For one numerical program, the water continuum is formally defined to be the residual absorption of

wings more than 25 cm^{-1} from line centers. Water vapor lines and continua, defined in this way, are shown as two distinct spectra in Figure 3. The $10\text{ }\mu\text{m}$ continuum is of great importance for climate studies because it controls a spectral region where energy can readily escape from the lower atmosphere to space.

Nitrogen, oxygen, and carbon dioxide molecules are all symmetric, and some or all vibration–rotation transitions are strictly forbidden. In close collisions, however, these symmetries are broken and transitions can take place for a very short time. Transitions for which this is of interest are the fundamental vibrational transitions of nitrogen and oxygen and the pure rotational transitions of oxygen, nitrogen, and carbon dioxide. Because a very short time is spent during collisions, the lines are very wide, and they overlap to form a featureless continuum.

Polymers may be formed during close collisions. Polymer bands have been detected in the visible and near-infrared spectra of oxygen. Again, absorption is continuous because of the short lifetime of the polymer.

Continua behave differently from line spectra. Line absorptions saturate as the path length increases, and for long paths the dependence upon path length becomes very slow. Continua do not saturate as readily as line spectra, and their relative importance increases at long absorption paths.

Radiance Algorithms

Equations [1] and [6] may be combined to give the net change of radiance for simultaneous absorption and thermal emission. The result is Schwarzschild's equation of transfer, eqn [12]:

$$\frac{dI_\nu}{d\tau_\nu} = I_\nu - B_\nu(T) \quad [12]$$

Equation [12] is incomplete. In general, the blackbody radiance should be replaced by a multiple-scattering and absorption source function.

If we integrate eqn [12] along a path in the l-direction, with the optical path (τ) varying from $\tau = 0$ at the place where the radiance is calculated, to a boundary at $\tau = \tau'$, where the radiance is given as a boundary condition, we obtain eqn [13]:

$$I_\nu(l, \tau = 0) = I_\nu(l, \tau = \tau') \exp(-\tau') + \int_0^{\tau'} B_\nu(\tau) \exp(-\tau) d\tau \quad [13]$$

The boundary is either space (for a downward-directed radiance) or the Earth's surface (for an upward-directed radiance). Equation [13] is valid for both thermal and solar radiation, with the difference that, in the solar spectrum (0.15–5 μm), the thermal source function is usually neglected, and the second term on the right of eqn [13] omitted. The source of solar radiation in the atmosphere (in the absence of scattering) is the first (boundary) term on the right of eqn [13].

From the solution of eqn [13], it is possible to construct the radiation flux by integrating over all directions, and its divergence (the negative heating rate, also frequently denoted as the cooling rate). The radiative heating rate is the fundamental drive for the atmosphere, and its calculation with adequate precision is an important task for radiation studies.

Equation [13] is a simple quadrature. Nevertheless, it is a major numerical task to perform it efficiently, flexibly with respect to changing input data, and accurately. In the United States, two tested programs are available: LBLRTM, originally developed at the US Air Force Research Laboratory and now at the Atmospheric and Environmental Research Radiative Transfer Working Group (<http://rtweb.aer.com/lblrtm.html>); and GENLN, developed at Oxford University and the National Center for Atmospheric Research (e-mail contact: edwards@ucar.edu). Both programs are monochromatic (so-called line-by-line codes). They are based upon the HITRAN database, adding those data on lineshapes and continua that are needed to complete the calculation. No physical approximations are employed. Both programs (and also Moderate-resolution Atmospheric Transmission (MODTRAN), discussed in this article) can be combined with scattering options.

Although modern computers can step rapidly through the thermal or solar spectrum with frequency steps smaller than the

narrowest lines, line-by-line calculations are too slow for weather or climate models and applications in remote sensing, especially hyperspectral remote sensing. These usually employ band model calculations, in which eqn [13] is integrated with respect to frequency over many lines, sometimes over entire vibration-rotation bands. The exponential functions are then replaced by more complex functions based partly on laboratory measurements and partly on theoretical analysis. Such methods are of limited accuracy, although, in recent years, the main sources of error have been overcome by means of different fast parameterization techniques. One group of techniques predicts the transmittances or radiances by using a limited number of monochromatic transmittances or radiances. The most well-known of these is the correlated- k distribution technique. The exponential-sum fitting transmittance, spectral-mapping, and optimal spectral-sampling techniques also belong to the same group. One advantage of using such techniques is the full compatibility with scattering options. Another group of techniques employs efficient schemes to predict the layers' optical depth (with or without convolution by the instrument response function) and then computes transmittances or radiances accordingly. Also, a faster model has been developed based on the principal component analysis, which takes advantage of the orthogonal properties of the principle components to compress the spectral information, and then the model predicts only the scores of principle components instead of radiances or transmittances at each frequency channel. These techniques are critical for better use of current hyperspectral observations taken from space, which normally contain radiances measured at thousands of channels.

MODTRAN is a band model program with a maximum resolution of 0.1 cm^{-1} . The latest version, MODTRAN5, was developed by the US Air Force Research Laboratory and Spectral Sciences Inc. (<http://modtran.org>), and also has options for both the traditional random-band model and correlated- k distribution technique. It is commonly used when speed is a consideration.

Radiation in the Earth's Atmosphere

Interaction with the Sun and with Space

Absorption of solar radiation in the atmosphere and emission of the atmosphere to space are concentrated in layers (Chapman layers). The altitude of the maximum of a Chapman layer for a given wavelength depends on the absorption coefficient (see Figure 4).

Boundary Fluxes

Figure 5 shows net solar and thermal fluxes for 100 km and for the Earth's surface, in midlatitudes. The differences between these two fluxes represent the total radiant energy gained or lost by the atmosphere. The calculation omits all scattering; consequently (and unrealistically), the solar flux is for the direct solar beam only. The global lower atmosphere, as a whole, loses the radiant energy, which is, in general, balanced by the latent heat release from the condensations of water vapor.

Figure 4 Altitudes of solar absorption and thermal emission. Heights of Chapman layers and primary absorbers for vertical radiances.

Heating Rates

Figure 6 shows the breakdown of the energy gained and lost to the atmosphere from **Figure 5**, with respect to altitude and principal species. Imbalances are the drivers for dynamical processes.

Radiative Equilibrium

The thermal terms in **Figure 6** are more sensitive to air temperature than are the solar terms. Consequently, the atmospheric temperature may be adjusted until the solar and thermal terms in **Figure 6** balance. This state (radiative equilibrium; see **Figure 7**) can exist only in an idealized, motionless atmosphere. Nevertheless, it offers an important heuristic basis for studying the state of the climate system (CS).

Thermodynamics of the Radiation Field

The thermodynamics of the radiation field is characterized by two intensive variables, temperature and pressure, and two extensive variables, energy and entropy; they are not independent, and all can be expressed in terms of the energy and the frequency.

Temperature

The brightness temperature is obtained by inverting eqn [2] with the ambient radiance in place of B_ν , and it is the temperature with which the radiation stream is in equilibrium.

Pressure

The radiation pressure is equal to one-third of the energy density. It can cause work to be done during an interaction with matter in motion, but, for atmospheric velocities, this work is negligible compared to changes of energy. Consequently, the heat interaction experienced by the atmosphere is the loss of the internal energy of the radiation (i.e., the negative divergence of the radiative energy flux).

Entropy

The entropy radiance (L_ν , defined in the same manner as the energy radiance) is a single-valued function of the energy radiance. For cavity radiation, the entropy radiance can be integrated over all frequencies to give eqn [14].

$$L = \int_0^\infty L_\nu d\nu = \frac{4}{3} \frac{\sigma}{\pi} T^3 \quad [14]$$

Figure 5 Upward thermal and downward solar net fluxes at 100 km and at the Earth's surface. Vertical fluxes have been calculated from MODTRAN. The conditions approximate global averages. The solar fluxes are for the direct solar beam only (zenith angle, 75.8°). All scattering and reflection terms are omitted. If scattering and reflection were included, the solar fluxes would be scaled back. The solar and thermal fluxes are plotted in such a manner that areas are proportional to energies, and scaled so that their maxima are equal. In absolute units, the areas of these curves are as follows: Sun, 100 km, 339.0 W m^{-2} ; Sun surface, 187.5 W m^{-2} ; Earth, 100 km, 253.9 W m^{-2} ; and Earth surface, 103.9 W m^{-2} . The differences between the 100 km and the surface fluxes represent the total energy gained (solar) or lost (thermal) by the atmosphere.

Figure 6 Atmospheric heating rates. These plots show the breakdown on the flux differences from [Figure 5](#) by altitude and by major species. The heating rate is divided by the volumetric heat capacity (ρc_p) and is expressed in K d^{-1} . The data correspond to those used in [Figure 5](#). The calculation was performed using a band model developed for the general circulation model CCM2 (the National Center for Atmospheric Research's Community Climate Model).

The absorption and emission of radiation (except in a constant-temperature enclosure) have an irreversible component. This arises because the brightness temperature of the radiation field will generally differ from the local kinetic temperature, and this difference must be thermalized through collisions. This is a disequilibrium process and, since it is assumed that the atmosphere is in local thermodynamic equilibrium, the

thermalization must, for consistency, be assumed to take place outside the CS. Consequently, the entropy increase that results from this irreversible process is accounted for by an increase of entropy in the radiation field, and has no direct significance for climate studies.

There is also a reversible component to the change of entropy during an interaction that, for the radiation field, is equal to but also the opposite sign of the corresponding change for the atmosphere. The rate of change of specific entropy for the atmosphere is given by [eqn \[15\]](#), where $\dot{q}_{\text{rad}}$ is the specific heating rate of the atmosphere.

$$\dot{s}_{\text{rad}} = \frac{\dot{q}_{\text{rad}}}{T} \quad [15]$$

The balance equation for entropy production in the entire CS may be written in the following form:

$$\int_{\text{CS}} (\dot{s}_{\text{mol}} + \dot{s}_{\text{rad}}) \rho dV = 0 \quad [16]$$

where dV is an element of volume, ρ is the density, and $\dot{s}_{\text{mol}}$ is the rate of change of specific entropy from irreversible molecular dissipative processes in the fluid. From the second law of thermodynamics, $\int_{\text{CS}} \dot{s}_{\text{mol}} \rho dV > 0$ so that $\int_{\text{CS}} \dot{s}_{\text{rad}} \rho dV < 0$ (i.e., radiation must extract entropy from the CS). According to [eqn \[15\]](#), this may be achieved if solar heating takes place at a higher temperature (lower altitude) than cooling by thermal radiation; this condition follows because most of the solar radiation is absorbed by the Earth's surface (see [Figure 5](#)).

Figure 7 Radiative equilibrium temperatures. Compared to the US standard atmosphere. Solar conditions correspond to those employed in [Figure 6](#). The CCM2 radiation model was used.

Units and Nomenclature

SI units are used throughout. All nonstandard nomenclatures are defined in the text.

Cloud-Radiative Processes

Q Fu, University of Washington, Seattle, WA, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Clouds consist of water droplets with typical diameters of $\sim 20\ \mu\text{m}$ or ice crystals with a typical size of $\sim 100\ \mu\text{m}$ suspended in the atmosphere. Cloud-radiative processes are the interactions between these cloud particles and electromagnetic radiation, including the scattering, absorption, and emission processes. Radiative transfer, which serves as a mechanism for exchanging energy within the Earth-atmosphere system and between this system and the rest of the universe, is strongly modified by clouds. An understanding of cloud-radiative processes and their effects on radiative transfer is fundamentally important in climate studies and remote sensing applications.

Refractive Indices of Water and Ice

The refractive indices of pure water and ice, as functions of wavelength, are needed to determine the scattering and absorption properties of cloud particles. The complex refractive index $m(\lambda) = m_r(\lambda) + im_i(\lambda)$, where λ is the free-space wavelength, m_r is the real part of the refractive index, and m_i is the imaginary part. The real part of a refractive index is the ratio of the free-space speed of light to the phase speed of an electromagnetic wave in the medium. The imaginary part of a refractive index is related to the absorption coefficient by $4\pi m_i/\lambda$. For a real refractive index, only scattering can take place. For a complex index, both scattering and absorption are possible.

The refractive indices for water and ice have been measured extensively, and are comprehensively reviewed and tabulated. Figure 1 shows the real and imaginary refractive indices for water and ice as functions of wavelength. The real refractive indices of water exhibit large deviations from those of ice for wavelengths greater than about $10\ \mu\text{m}$. The imaginary refractive index of ice

shows a maximum in absorption at about $1.6\ \mu\text{m}$, where water exhibits a minimum. On the other hand, water has much greater absorption than ice at wavelengths larger than $10\ \mu\text{m}$.

The imaginary refractive indices for both ice and water are negligibly small in the UV and visible regions, but increase greatly in the near-infrared.

Light Scattering and Absorption by Cloud Particles

Scattering is a physical process by which a particle in the path of an electromagnetic wave continuously abstracts energy from the incident wave and reradiates it in all directions. The angular distribution of the scattered energy from a particle is described using a scattering phase function. Scattering is often accompanied by absorption, which results in the transfer of energy from the radiation field to the heat budget. The beam of radiation may be attenuated by both absorption and scattering, which together are called the extinction. In the field of light scattering and radiative transfer, it is customary to use the term

Figure 1 Refractive indices for water (red lines) and ice (blue lines) as functions of wavelength: (a) Real part and (b) imaginary part.

'cross-section,' which is analogous to the geometric cross-sectional area of a particle, to denote the amount of energy removed from the original beam by the particle. An extinction cross-section is the sum of the scattering and absorption cross-sections. The extinction (scattering or absorption) efficiency is the ratio of an extinction (scattering or absorption) cross-section to a particle's geometric cross-sectional area.

Light scattering and absorption by cloud particles depend on the size and shape of the particles, the wavelength of radiation, the particles' refractive indices, and the viewing geometry. The interactions of radiation and liquid droplets in water clouds are well described by Mie theory, a complete solution of Maxwell's equations for a plane electromagnetic wave incident on a dielectric sphere. By considering the scattered field at a large distance from a sphere, we can derive the scattering and extinction cross-sections and the scattering phase function.

Figure 2 shows the extinction (Q_e), scattering (Q_s), and absorption (Q_a) efficiencies and the asymmetry factor as functions of the size parameter, defined as $2\pi r/\lambda$, where r is the radius of the sphere. The asymmetry factor is the first moment of the scattering phase function, which is positive or negative respectively as the particle scatters more energy into the forward or backward direction. The refractive indices used are those of water at wavelengths of 0.55 and 11 μm . In the limit of large size parameters, the extinction efficiency approaches a value of 2.

For $m_i = 0$, there is no absorption, so that $Q_s = Q_e \cdot Q_s$ (or Q_e) in this case shows a series of major maxima and minima and ripples. The major maxima and minima are due to interference of light diffracted and transmitted by the sphere, whereas the ripple arises from edge rays that are grazing and traveling the sphere, spewing off energy in all directions. Q_s approaches 2 for large size parameters, which applies to the interaction of cloud droplets with visible radiation. Since all

visible wavelengths are scattered nearly equally well, clouds therefore appear white.

At 11 μm , the absorption efficiency is on the order of 1 for the size parameters larger than ~ 6 . Therefore, cloud droplets absorb nearly all of the infrared radiation incident on them. They act essentially as black bodies. Scattering efficiencies in the infrared with large size parameters result mainly from the diffraction around the sphere.

In clouds, there is usually a distribution of droplet sizes. Suppose that $N(r)dr$ is the number of droplets per unit volume in the radius range r to $r + dr$. If the scatterers are sufficiently far apart (many wavelengths) that they act independently, the extinction coefficient of cloud droplets, which is the total extinction cross-sections of cloud droplets per unit volume, is given by $\beta_e = \int \pi r^2 Q_e N(r) dr$, where Q_e is the extinction efficiency. The scattering (absorption) coefficient is obtained similarly but by replacing the extinction efficiency with the scattering (absorption) efficiency. The ratio of scattering to extinction coefficients is called the single-scattering albedo of cloud droplets. In the geometric limit (i.e., the limit of large size parameters), we have $\beta_e = \frac{1.5 \text{ LWC}}{\rho_w r_e}$, where

LWC is cloud water content (i.e., $\frac{4}{3} \pi \rho_w \int r^3 N(r) dr$), r_e the effective radius (i.e., $\int r^3 N(r) dr / \int r^2 N(r) dr$), and ρ_w the liquid water density. The vertical integration of the extinction coefficient gives the cloud optical depth that is the total extinction cross-sections of cloud droplets in a vertical column per unit surface area.

Cirrus clouds are composed almost exclusively of nonspherical ice crystals, with a wide range of shapes, such as columns, plates, hollow columns, bullet rosettes, aggregates, and so on. The familiar halos associated with cirrus clouds

Figure 2 (a) Extinction (Q_e), scattering (Q_s), and absorption (Q_a) efficiencies and (b) the asymmetry factor of spheres as functions of size parameters. The refractive indices (m) of 1.333 and $1.153 + 0.0968i$ are those of water at wavelengths of 0.55 and 11 μm .

result from prismatic crystals with the hexagonal structure. Unlike the scattering of light by spherical water droplets, there is no general solution for light scattering and absorption by nonspherical ice particles. Geometric optics, essentially ray tracing, is often used with nonspherical ice particles having large size parameters, while numerical solutions of Maxwell's equations are used with small size parameters. Key gaps, however, still exist in our knowledge of light scattering and absorption by complex ice particles.

Radiative Transfer in a Cloudy Atmosphere

The influence of clouds on atmospheric radiation fields is governed by a radiative transfer equation. If the intensity of radiation I_λ becomes $I_\lambda + dI_\lambda$ after traversing a thickness ds in the direction of its propagation, then we can write eqn [1], where $\beta_{e,\lambda}$ is the extinction coefficient for radiation of wavelength λ , and j_λ is the source-function coefficient. The first term on the right-hand side of eqn [1] represents the reduction in the intensity caused by absorption and scattering of radiation by the atmosphere and clouds; the second term represents the contribution from emission of the layer plus a result of the radiation redirected from all other directions by the scattering process into the direction under consideration. By defining the source function $J_\lambda = j_\lambda/\beta_{e,\lambda}$, we obtain eqn [2].

$$dI_\lambda = -\beta_{e,\lambda} I_\lambda ds + j_\lambda ds \quad [1]$$

$$\frac{dI_\lambda}{\beta_{e,\lambda} ds} = -I_\lambda + J_\lambda \quad [2]$$

Knowledge of scattering and absorption coefficients and the scattering phase function is required for determination of the source function. In local thermodynamic equilibrium, the source function associated with an emission process is proportional to the Planck function, a known function of frequency and temperature. The scattering source function involves an integral over all directions of incidence, which transforms the radiative transfer equation into an integrodifferential equation. This feature of the scattering process greatly increases the complexity of radiation calculations. Many efficient and accurate methods of solving the radiative transfer equation have been developed for numerical models and remote sensing applications by assuming that clouds are uniform and infinite in the horizontal, which is called the plane-parallel cloud assumption.

For the calculation of radiative transfer in cloudy atmospheres, we must also consider gaseous absorption. The number of monochromatic calculations that are needed for molecular line spectra is so great that they can be used only for rare occasions. The correlated-k method solves this problem by approximating frequency integrals over line spectra by sums over a few finite intervals of new independent variables.

Clouds reflect and absorb solar radiation. Solutions of the radiative transfer equation can be used to determine the radiative properties of clouds under the plane-parallel assumption. If the cloud particle size distribution and vertical distribution of humidity are given, then the cloud albedo and absorption of solar radiation depend on the cloud water path and the solar zenith angle. The cloud water path is the total mass of cloud water in

a vertical column of atmosphere per unit of surface area. The cloud optical depth is proportional to the cloud water path and inversely proportional to the effective radius of cloud droplets.

The cloud albedo increases with the cloud water path and also with the solar zenith angle. It increases with the cloud water path most rapidly for smaller values of cloud water paths, and approaches a limit for very large cloud water paths. The absorption of solar radiation by plane-parallel clouds decreases with increasing solar zenith angle, but increases with the cloud water path. For a typical water droplet size distribution and a solar zenith angle of 60° , the cloud albedo can range from $\sim 25\%$ to over 80% , and its absorption from ~ 3 to $\sim 11\%$, as the cloud water path increases from 10 to 1000 gm^{-2} .

The cloud albedo and absorption of solar radiation are also sensitive to the cloud particle size. Keeping the cloud water path fixed, the albedo is larger for smaller droplets, mainly because these present a larger surface area for the same mass.

Clouds effectively absorb and emit terrestrial radiation. With cloud water paths greater than about 20 gm^{-2} , water clouds become opaque to terrestrial radiation. For most water clouds, it is a good approximation to assume that cloud surfaces absorb and emit terrestrial radiation like black bodies. Unlike water clouds, cirrus clouds are usually partially transparent to terrestrial radiation owing to their larger cloud particle sizes and smaller cloud water paths. Recent studies also suggest that the neglect of scattering processes in the infrared for cloudy atmospheres leads to a few Wm^{-2} errors in estimating the outgoing longwave radiation.

Contrary to the plane-parallel cloud assumption, real clouds are horizontally finite and inhomogeneous. With an overhead sun, solar radiation may leak from the sides of clouds, which leads to increased transmission and absorption of solar radiation throughout the atmosphere. At large solar zenith angles, the reflected and absorbed solar radiation increase, owing to the increased interception and reflection of solar radiation by cloud sides. Finite clouds also have significant effects on the transfer of long-wave radiation.

Non-Local Thermodynamic Equilibrium

M López-Puertas and B Funke, Instituto de Astrofísica de Andalucía, CSIC, Granada, Spain

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

This article introduces the concept of non-local thermodynamic equilibrium (non-LTE) in planetary atmospheres and provides a basic theoretical framework of non-LTE radiative transfer and statistical equilibrium of molecular states. Accurate and approximate solutions of the non-LTE problem are discussed. A climatology of non-LTE populations of the most important vibrational levels of the atmospheric species is provided. Examples of non-LTE applications in general circulation models and the remote sensing of the Earth's and other planetary atmospheres are given.

Introduction

The atmosphere, viewed as a thermodynamic system, is never in true thermodynamic equilibrium at any level. A given parcel of air is always in the process of changing its properties through the exchange of particles and photons with its surroundings, through collisions between molecules, and through chemical changes. It can, however, be in a state known as 'local' thermodynamic equilibrium (LTE), a concept that permits calculations of radiative transfer in the atmosphere, and its energy exchanges (both internally and with its upper and lower boundaries), to be made relatively simply. In general, LTE applies if the populations of the energy levels within a molecule are the same, or nearly the same, as they would be under true thermodynamic equilibrium conditions. LTE occurs when collisions are so frequent that the energy level populations depend predominantly on the local kinetic temperature, as defined by the Maxwellian statistics of molecular motion. It is worth noting that this definition of LTE does not impose restrictions upon the radiation field of the emission involved. That is, unlike in strict thermodynamic equilibrium, in LTE the local radiation field is not necessarily described by Planck's function at the local temperature. Hence, LTE is compatible with a net gain or loss of radiative energy (heating or cooling) by the gas in the transition in question, provided that collisions are quick enough to supplement the energy sink and to keep the population of the excited state coupled with the translational reservoir.

Conversely, non-LTE arises when the 'internal' temperature of a representative molecule, as determined by the statistics of the relative populations of the vibrational and rotational energy levels, becomes different from the 'external' temperature, as determined by the statistics of the velocity distribution of the molecules making up a parcel of gas. Any difference depends primarily on the mean rate at which collisions take place between the individual molecules, which in turn depends mainly on the number density, and thus on the pressure and temperature of the sample. Since the pressure dependence usually dominates, non-LTE effects in atmospheres are mainly of importance at the higher altitudes, that is, in the upper stratosphere and above.

Basic non-LTE theory and most theoretical models of planetary atmospheres deal with the transfer of energy as (primarily infrared) radiation within an atmosphere with a fixed composition and no fluid dynamics. A refinement

would be to include basic photochemistry (i.e., the situation where photon-molecule encounters lead to the breakup of the molecule and the subsequent formation of a different stable or quasistable species). This is, of course, another example of a nonequilibrium process, which depends on the nature of the photon field and often the internal state of the molecule also.

Important applications of non-LTE theory in the atmosphere include the calculation of thermal cooling and solar heating rates. Dynamical models of the upper atmosphere are very limited if they do not include realistic calculations of the heating and cooling that drive the motions, and these are strongly affected by non-LTE. Furthermore, the growth of infrared detector technology in recent decades has allowed sounding of the middle and upper atmosphere using the limb emission measured by infrared sensors on satellites. The interpretation of these data in terms of temperature and composition profiles depends on non-LTE radiative transfer theory, especially in the middle and upper atmosphere.

Breakdown of Local Thermodynamic Equilibrium

The concept of LTE was introduced by Schwarzschild in 1906 in his study of stellar atmospheres. He realized that, in a star just as in a planetary atmosphere, any individual parcel of gas is not isolated, and, in principle, no equilibrium can be defined. However, the concept of equilibrium is so valuable in practice that it is worth looking for situations where it can be assumed as a close approximation to reality. Thus, a rotational or vibrational energy level is in LTE if its population is given by Boltzmann's law at the local kinetic temperature, T , that is,

$$\frac{n_{v,r}}{n_0} = \frac{g_{v,r}}{g_0} \exp\left(-\frac{E_{v,r}}{kT}\right) \quad [1]$$

where $n_{v,r}$ is the number density of the upper (vibrational or rotational) state, $E_{v,r}$ is its energy, n_0 is the number density of the ground state, $g_{v,r}$ and g_0 are their respective degeneracies, and k is the Boltzmann constant. The emission from the level is then characterized by the Planck function, $B(T)$, at temperature T .

When the population of the level deviates from Boltzmann's law, we say that the energy level is in non-LTE or has a non-LTE population. This can be characterized by introducing an 'excitation' (vibrational or rotational) temperature $T_{v,r}$, defined by

eqn [1] with T replaced by $T_{v,r}$. It then follows that if the vibrational or rotational temperature of an energy level differs from the local kinetic temperature, the level is in vibrational or rotational non-LTE. Similarly, the radiance emitted by the level considered is said to be non-LTE emission and so is the cooling or heating it produces.

For a real atmospheric parcel containing different kinds of molecules, some can be in LTE and others not. In fact, it is possible (and, at intermediate pressures like those found in the upper stratosphere, quite usual) for one internal energy state to be in LTE, and another not, in the same individual molecule (see Table 1). The reason for the dependence on height is the dependence on pressure of the collision frequency, and the different efficiencies for transferring energy to vibrational modes during collisions. In the atmosphere, pressure and therefore frequency of collisions fall off with height. Thus, we should expect a given transition to be more likely to be in non-LTE in the upper atmosphere.

Another important parameter influencing the height at which non-LTE occurs is the energy of the transition. For those corresponding to small energy jumps, the average number of collisions required to keep the levels in equilibrium is smaller, so they can be in LTE up to higher altitudes in the atmosphere. For example, the CO₂ 4.3 μm band starts to depart from LTE at approximately 50 km, while the O(³P) states that emit at 63 μm and the purely rotational levels of virtually all atmospheric molecules, emitting in the microwave part of the spectrum, are in LTE up to the high thermosphere.

There are two common ways in which the internal states of any given molecule can ‘know’ what the ensemble of molecules in the gas is doing. One is through collisions, and the other through exchanging photons (Figure 1). If the former dominates, then LTE is normally guaranteed, but not necessarily

where the populations are controlled by the transfer of radiation. Under optically thin conditions, the absolute intensity, directional distribution, and frequency spectrum of the radiation field may have little or no relation to the Planck function at the local kinetic temperature, and hence drives the level populations to non-LTE. The reverse may be true under optically thick conditions, but then collisions are usually plentiful as well.

Depending on the processes at work, we can generally distinguish between the following non-LTE situations:

1. Classical non-LTE, where, in the absence of a strong radiative source, thermal collisions are not fast enough to supply the energy lost by spontaneous emission and so the population of the excited state is smaller than that corresponding to LTE (e.g., CO₂(0,1¹,0) in Figure 2). The level at which a transition departs from LTE can be estimated in such cases as that in which the collisional relaxation time is of the same order as the spontaneous radiative lifetime, particularly if the transition is optically thin at this height. For optically thick conditions, a better approximation is the altitude at which the thermal losses equal the spontaneous emission multiplied by the probability of photon escape to space.
2. The internal atmospheric radiation field can cause a breakdown of LTE when it is responsible for overpopulating the excited level with respect to the Boltzmann distribution. This situation is common for molecular states that give rise to weak infrared bands in the cold upper mesosphere, since their populations are sensitive to the flux of infrared photons from the warm lower atmosphere (e.g., the (0,1¹,0) level of the ¹⁶O¹²C¹⁷O isotopologue (627) and H₂O(010) in Figure 2).

Table 1 Approximate altitude of non-LTE departure of the most important energy levels of atmospheric species

Species	Band origin wavelength (μm)	Energy level	Approximate altitude ^a (km)
CO ₂	15	01 ¹ 0	90
CO ₂	15	02 ² 0	80
CO ₂	15	03 ³ 0	70
CO ₂	10	00 ⁰ 1	50
CO ₂	4.3	00 ⁰ 1, 01 ¹ 1	50
CO ₂	4.3	02 ⁰ 1, 02 ² 1, 10 ⁰ 1	40
CO ₂	2.7	02 ⁰ 1, 10 ⁰ 1	40
CO	4.6	1	40
O ₃	10	001, 100	70
O ₃	10	$\nu_3 = 2,3; 4; \nu_3 > 4$	60; 50; 30
O ₃	14.8	0,1,0	70
H ₂ O	6.3	010; 020	60; 40
H ₂ O	2.7	100, 001	10
CH ₄	7.6	ν_4	70
CH ₄	6.5	ν_2	70
NO	5.3	1	20
N ₂ O	17	010, 020	80
N ₂ O	7.8	100	75
N ₂ O	4.5	001	50
NO ₂	6.2	001; $\nu_3 > 1$	50; 10
O(³ P)	63	O(³ P ₁)	>200

^aThe altitude of LTE breakdown depends on the atmospheric conditions (latitude and season) and the solar illumination (see Figures S2–S27). For some levels, it changes considerably from day to night. The values are given here for daytime, when this altitude is lower. Note that non-LTE effects are observed at lower tangent heights in limb radiances.

Figure 1 Processes affecting the populations of vibrational levels in the atmosphere.

Figure 2 Vibrational temperatures for some species and levels for a typical kinetic temperature profile T_k illustrating the different processes causing non-LTE populations.

3. Non-LTE breaks down when the absorption of the strong solar radiation field is the prime process for the population of the excited levels. This occurs mainly for states that emit in the near-infrared part of the spectrum (e.g., the (0,0,1) level of CO_2 in [Figure 2](#)).
4. There are also situations where molecules are excited and de-excited by processes such as chemical recombination, photochemical reactions, electronic–vibrational and vibrational–vibrational energy transfers, dissociative recombination, and charged particles collisions (e.g., $\text{O}_3(\nu_3 = 2)$ in [Figure 2](#) is an example of the chemical recombination that forms O_3). These are also largely responsible for the

atmospheric emissions that constitute the terrestrial day-glow, night-glow, and auroral spectra, which historically have not been referred to as non-LTE emissions; however, since the populations of the excited states that produce these phenomena are far from a Boltzmann distribution at the local kinetic temperature, they should come under this heading.

Basic Non-LTE Theory

Historically, the solution of non-LTE situations has been linked to the development of radiative transfer theory and to the description of the radiating properties of matter. After the first treatment by Milne in 1930 of radiative transfer under non-LTE conditions for stellar atmospheres, this subject has been extensively studied in astrophysics, mainly to interpret stellar spectra and to study line formation in hot stars.

In 1949, Spitzer first pointed out the possibility that at the low pressures found in the upper atmosphere, the radiative field could upset the state of LTE. No quantitative treatment was given, however. The first application of a non-LTE formulation in the terrestrial atmosphere was by Curtis and Goody in their 1956 study of the CO_2 15 μm cooling rate in the mesosphere. They formulated the problem for the simplest case of a two-level transition, including only thermal collisions and radiative processes. At the same time, coinciding with the development of the first electronic computers, Curtis devised a linear parameterization of the radiative transfer equation to calculate the heating rates induced by the CO_2 15 μm bands.

To obtain the population of n_2 and n_1 , and then the vibrational temperatures from [eqn \[1\]](#), as shown in [Figure 2](#),

we consider the statistical equilibrium equation. Let us consider that the two levels are connected (Figure 1) by

1. radiative processes (spontaneous emission, induced emission, and absorption) through the vibration-rotation band (2-1);
2. thermal collisions or vibrational-translational (V-T) processes of this form:

$$k_t : n(2) + M \rightleftharpoons n(1) + M + \Delta E \quad [2]$$

where M is any air molecule, and $\Delta E = E_2 - E_1 = h\nu_0$ is the energy difference of the upper and lower levels;

3. nonthermal collisional processes of this kind:

$$k_{vv'} : C(v) + n(1) \rightleftharpoons n(2) + C(v') + \Delta E_v \quad [3]$$

$$k_{ev} : N^* + n(1) \rightarrow n(2) + N + \Delta E_{ev} \quad [4]$$

$$k_c : A + B + M \rightarrow n(2) + M \quad [5]$$

at rates $k_{vv'}$, k_{ev} , and k_c . $C(v)$ is an atmospheric molecule excited in vibrational level v before, and in v' after, the collision; and N^* is an excited atom or a molecule electronically or vibrationally excited. $\Delta E_v = E_v - E_{v'} - h\nu_0$ and $\Delta E_{ev} = E^* - h\nu_0$ are the energy excesses, with E^* being the energy of N^* .

The population of n_2 is then given by

$$\frac{n_2}{n_1} = \frac{B_{12}\bar{L}_{\Delta\nu} + p_t + p_{nt}}{A_{21} + B_{21}\bar{L}_{\Delta\nu} + l_t + l_{nt}} \quad [6]$$

where A_{21} , B_{21} , and B_{12} are the Einstein coefficients for spontaneous emission, induced emission, and absorption, respectively. $p_t = k'_t[M]$ is the thermal collisional production, where k'_t is the rate coefficient of process (eqn [2]) in the reverse direction, related to k_t by a detailed balance:

$$\frac{k'_t}{k_t} = \frac{g_2}{g_1} \exp\left(-\frac{E_2 - E_1}{kT}\right) \quad [7]$$

$p_{nt} = k_{vv}[C(v)] + k_{ev}[N^*] + k_c[A][B]/n_1$ is the specific production rate of n_2 molecules due to the nonthermal processes (eqns [3-5]), and $l_t = k_t[M]$ and $l_{nt} = k'_{vv}[C(v')]$ are the specific loss rates of n_2 in thermal (eqn [2]) and nonthermal (eqn [3]) processes. $\bar{L}_{\Delta\nu}$ is the mean radiance averaged over the spectral interval of the band, $\Delta\nu$, defined by

$$\bar{L}_{\Delta\nu} = \frac{1}{4\pi S} \int_{\Omega} \int_{\Delta\nu} L_{\nu} k_{\nu} d\nu d\Omega \quad [8]$$

where k_{ν} is the absorption coefficient, $S = \int k_{\nu} d\nu$ is the band strength, and Ω is the solid angle.

In order to get the population n_2 , we need to know the mean radiance $\bar{L}_{\Delta\nu}$, which is governed by the radiative transfer equation that, for a stratified atmosphere, takes the following form:

$$\mu \frac{dL_{\nu}(z, \mu)}{dz} = -k_{\nu} n_a [L_{\nu}(z, \mu) - J_{\nu}(z)] \quad [9]$$

where z is altitude; $\mu = \cos(\theta)$, with θ being the angle measured from the vertical; n_a is the number density of absorbing molecules; and J is the source function of the (2-1) band.

To complete the system, we need the expression that relates the source function with the population of the upper and lower states given, for an infrared transition, by

$$J_{\nu_0} = \frac{2h\nu_0^3}{c^2} \left[\frac{n_1 g_2}{n_2 g_1} - 1 \right]^{-1} \quad [10]$$

Thus, from the solution of the statistical equilibrium (eqn [6]) and the radiative transfer (eqn [9]), we can obtain the population of the upper state n_2 and the source function J_{ν_0} .

In addition to the non-LTE populations, we are also generally interested in the heating and cooling rates produced by the transitions between the energy states. The heating rate h (or, more precisely, the divergence of the radiative flux) of the band arising from the levels n_2 and n_1 can then be computed, once n_2 and the source function J_{ν_0} are known, by using

$$h = 4\pi S n_a [\bar{L}_{\Delta\nu} - J_{\nu_0}] \quad [11]$$

When interested in only the cooling and heating rates but not the populations, one may solve the problem by solving the statistical equilibrium equation (eqn [6]) and the radiative transfer equation in the form of eqn [11].

Simple Solutions of Non-LTE

One of the simplest cases of non-LTE is to assume that the excitation from absorption of radiation is negligible while radiative losses are important. The problem is then reduced to a 'local' solution. In this case, there are several approaches depending on which radiative losses we consider. The most extreme case is to assume that all photons emitted are lost and none are reabsorbed. The approach is usually called 'total escape to space.' In this case, the population can be approached by

$$\frac{n_2}{n_1} = \left(\frac{l_t}{A_{21} + l_t} \right) \frac{\bar{n}_2}{\bar{n}_1}, \quad J_{\nu_0} \approx \frac{B_{\nu_0}}{1 + A_{21}/l_t} \quad [12]$$

where the overbar denotes LTE populations. Under these conditions, we expect non-LTE to set in at those altitudes where l_t is significant or smaller than A_{21} . The density of n_2 will then be smaller than that corresponding to LTE.

For these conditions of no significant radiative excitation, the heating rate can be approximated by

$$h_{12} \approx -n_2 A_{21} h\nu_0 \quad [13]$$

and, including n_2 from eqn [12], we get

$$h_{12} \approx -\left(\frac{A_{21} l_t n_1}{A_{21} + l_t} \right) \frac{\bar{n}_2}{\bar{n}_1} h\nu_0 \quad [14]$$

A similar approach is to assume that only half of the emitted photons are lost; this is usually called 'escape to space.' This is normally interpreted as follows: photons emitted to the hemisphere above the considered layer are lost, while those emitted to the downward denser atmosphere are fully recovered by absorption from the layers below. The expressions for the non-LTE populations and heating rates are those of eqns [12] and [14] but include dividing A_{21} by 2.

A further refinement along this line of 'local' approaches is the 'cool-to-space' approach. This introduces the concept of the 'escape probability' function that gives the probability that

a photon, emitted at an altitude z , escapes to space in any direction in the upper hemisphere. This is defined by

$$\Gamma(z) = \frac{1}{S} \int_{\Delta\nu} \int_0^1 k_\nu(z) \exp[-\tau_\nu(z, \infty, \mu)] d\mu d\nu \quad [15]$$

where $\tau_\nu(z, \infty, \mu)$ is the optical depth at direction $\mu = \cos(\theta)$. The non-LTE populations, source function, and heating rate for this approach are also given by eqns [12] and [14] by multiplying A_{21} by $\Gamma/2$. These expressions tend to those for the ‘escape-to-space’ approach, where the band becomes optically thin and Γ tends to unity. For optically thick conditions, $\Gamma \rightarrow 0$ and hence $J \rightarrow B$, the upper level remains in LTE even though the radiative relaxation time may be significantly smaller than the time between thermal collisions. This approach describes very well the departure from LTE of levels where the band originating from them is optically thick and a few collisions per second are then enough to keep the levels in LTE. A typical example is the $\text{CO}_2(0,1,0)$ level in the atmospheres of Mars and Venus. Figure 3 illustrates the cooling rates for the CO_2 15 μm fundamental band in the atmosphere under those approximations and compared to the full non-LTE solution.

A further approximation, plausible at high altitudes, is to assume that the thermal collisional losses are much smaller than the radiative emissions (i.e., $A_{21} \gg l_t$). Then, eqns [12] and [14] reduce to

$$\frac{n_2}{n_1} \approx \frac{l_t}{A_{21}} \frac{g_2}{g_1} \exp\left(-\frac{h\nu_0}{kT}\right) \quad [16]$$

$$h_{12} \approx -l_t n_1 \frac{g_2}{g_1} \exp\left(-\frac{h\nu_0}{kT}\right) h\nu_0 \quad [17]$$

Note that the heating rate (which is actually cooling) is solely controlled by the specific rate of thermal collisions, l_t , independent of the value of A_{21} , and therefore independent of whether the radiative losses are A_{21} or $A_{21}/2$.

There is another common situation where we have a strong radiation source, usually the Sun, which is so strong that the radiative exchange between layers can be neglected and we still have a ‘local’ solution. Productions by thermal collisions can then also be neglected, but not the losses. In this case, the population can be approached by

$$\frac{n_2}{n_1} = \frac{I}{A_{21} + l_t} \quad [18]$$

where I is the photoabsorption coefficient given by

$$I(z) = \int_{\Delta\nu} \Phi_{\nu,\infty} k_\nu(z) \exp\left[-\int_z^\infty \frac{k_\nu(z') n_a(z')}{\cos \chi} dz'\right] d\nu \quad [19]$$

where $\Phi_{\nu,\infty}$ is the solar flux at the top of the atmosphere, and χ is the solar zenith angle. Note that the curvature of the Earth has been neglected here. The heating rate can be obtained, from eqns [10], [11], and [18], by

$$h_{12} \approx \frac{l_t}{A_{21} + l_t} n_1 I h\nu_0 \quad [20]$$

In the highest altitudes, where thermal losses are negligible, $l_t \rightarrow 0$, the heating rate tends to be zero. That is, all of the radiation absorbed from the Sun is reemitted and no net kinetic energy is transferred to the atmospheric molecules. Opposite, at the lowest regions, where $l_t \gg A_{21}$, almost all of the solar energy absorbed, $n_1 I h\nu_0$, is converted to kinetic energy.

Non-LTE Models

The theory outlined in this article has been incorporated into models that calculate the non-LTE populations of the vibrational levels of the atmospheric species, and that derive from these the cooling and heating rates produced by the transitions that occur between them. The populations are useful mainly for

Figure 3 Cooling rates of the CO_2 15 μm fundamental band in the atmosphere for LTE, non-LTE, and the ‘total scape to space’ (TES) and ‘cool-to-space’ (CTS) approximations.

the interpretation of remote sensing data, while heating rate calculations are an essential component of the general circulation models of the upper atmosphere.

The non-LTE models solve the system formed by the statistical equilibrium equation for each of the molecular vibrational energy levels, and the radiative transfer equation for the significant transitions that take place between them. All thermal and nonthermal collisional processes involved in excitation and deexcitation of the levels must be included in the statistical equilibrium equation (eqn [6]). The radiative transfer equation (eqn [9]) must, in the non-LTE case, take account of (1) spontaneous emission; (2) the absorption of radiation from external sources, especially tropospheric, stratospheric, and solar radiation; and (3) the transfer of photons between each atmospheric layer and every other layer. The last term should incorporate, as for the LTE case, the frequency variation of the atmospheric absorption coefficient, which includes a large number of vibration-rotation lines with shapes that vary with temperature and pressure. The solution requires the integration of the radiative transfer equation over frequency and over solid angle to obtain the flux transmittances, followed by the solution over altitude of the coupled system of radiative transfer and statistical equilibrium equations. When the V-V energy exchange between vibrational levels with non-LTE populations is very fast, the coupled equations of statistical equilibrium for all the affected levels and of radiative transfer for all bands originating from those levels have to be solved simultaneously in order to obtain accurate populations.

This is achieved by inversion, iteration, or a combination of the two. A popular and flexible method for performing the numerical integration is that originally suggested by Curtis, which is based on the replacement of the integration over height by a summation over the atmospheric layers. It provides both the populations of the energy levels and the cooling and heating rates, and gives information about cooling to space and the radiative exchange between layers. The Curtis matrix method can be used to calculate cooling rates under LTE conditions as well, and in fact it was originally derived for that purpose. Another commonly used approach is the Lambda iteration, which alternates statistical equilibrium equation calculations, involving all energy levels, with radiative transfer calculations, involving all atmospheric layers. This technique is a rigorous approach, although it usually has the disadvantage of slow convergence in non-LTE situations driven by strong absorption and emission (i.e., optically thick conditions). Nevertheless, different acceleration strategies have been devised and employed in practical applications. In practice, when many energy levels and transitions are involved and are strongly coupled by collisional and/or radiative processes, models tend to use a combination of both techniques.

Non-LTE radiative transfer models represent a formidable computational task, and approximations need to be made whenever possible. Those that are often assumed include neglecting stimulated emission, assuming rotational LTE, grouping levels with very similar energies into resonant sets that can be treated as a single level, and neglecting overlapping between spectral lines of different bands. The most difficult situation is that where there is overlapping between the lines of different bands. Because of the different source

functions in each band, it then becomes necessary to evaluate the radiative transfer equation for each fine-mesh frequency point.

The usual inputs for the non-LTE models are the pressure, temperature, and composition profiles; the details of the relevant collisional thermal and nonthermal processes; and the spectroscopic line data to perform the radiative transfer calculation. Knowledge of the collisional activation and deactivation rates, energy transfer (V-T, V-V, or electronic to vibration) collisional rates and efficiencies, and nascent distributions in chemical reactions is the key input to the models, and the accuracy of the computed populations heavily relies on their uncertainties. In that sense, the models require laboratory measurements of those parameters in many cases, not to mention their dependencies on temperature that can range from 100 to 1000 K. For certain species and/or energy levels, the collisional rates have not been measured (e.g., for the deexcitation of high-energy states). Then, approximations are frequently used, as the harmonic oscillator approach. Spectroscopic line data are also very important. This is normally taken from compilations as HITRAN and GEISA. However, it is rather common that, for transitions from high energy levels and hot and overtone bands, information is missing, and approaches and theoretical approximations must then be used.

The typical outputs of the models are the non-LTE populations, frequently expressed in terms of the vibrational temperatures as described in this article and shown in Figure 2, and cooling or heating rates, like those shown in Figure 3.

Since the first model in 1956 for the CO₂ 15 μ m band, models have been developed for many other vibrational energy levels and infrared bands of this species; those of O₃, H₂O, N₂, NO, CO, and OH; and, more recently, those of CH₄, NO₂, N₂O, HNO₃, O₂, and HCN.

Non-LTE Populations

The non-LTE populations are normally used to calculate the emitted radiances or absorption spectra measured by remote sensing instruments, using a further radiative transfer code often referred to as the 'forward model' to distinguish it from the inverse procedure that is used to work back from radiances or spectra to retrieve the atmospheric variables of interest.

CO₂ is an example of an important atmospheric molecule that has many vibrational levels and whose populations are interdependent over extended atmospheric regions and originate many important transitions at 15, 10, 4.3, and 2.7 μ m. The first vibrational levels of N₂ and O₂ also need to be considered with those of CO₂ because, due to their resonances with the CO₂($v_1, v_2, 1$), H₂O(0, $v_2, 0$), and CH₄(v_2, v_4) levels, they play an important role in redistributing the excitation energy between these states via V-V collisional transfer (see Figure S1). The solution of this system requires, then, a complex and interactive model. Non-LTE populations are normally given in the form of vibrational temperatures, which are easier to understand physically, have a quick grasp of their departure from LTE, and, as population ratios relative to LTE, are very useful for radiance computations (see eqn [25]).

The variability of non-LTE populations in the atmosphere depends principally on the kinetic temperature structure and illumination conditions. Thus, the departure from LTE as well as the vibrational temperatures of the CO₂ energy levels vary significantly with the latitude, season, and illumination conditions of the atmosphere (see Figures S2 and S3). Non-LTE population climatologies for the energy levels of other important atmospheric species (e.g., H₂O, O₃, N₂O, CO, CH₄, O₂, NO, NO₂, HNO₃, OH, N₂, and HCN) are nowadays also available (see Figures S4–S27).

Cooling and Heating Rates

The reduction in collisional excitation that occurs in non-LTE situations leads to less efficient transfer between thermal kinetic energy and radiation, and then generally reduces the rate at which the atmosphere cools to space. Less obviously, it can affect the way in which the energy from the Sun is absorbed as well: the lack of frequent collisions prevents the energy absorbed from the solar radiation from being efficiently thermalized, and so influences the net heating rates. A quantitative understanding of non-LTE is therefore of value not only to improve our knowledge of processes in the upper atmosphere and to derive accurate temperature and constituent abundances from remote sensing measurements, but also to understand the energy budget of the region.

The non-LTE effect on cooling can be easily illustrated for the typical situation in the atmosphere where a band is optically thin and its upper level is excited only by thermal collisions and deexcited by spontaneous radiation (see eqn [16]). Then, the non-LTE and LTE cooling rates, $q = -h$, are related, from eqns [13] and [16] and eqn [1] for n_2 in LTE, by

$$\frac{q}{q^{\text{LTE}}} = \frac{k_t[M]}{A_{21}} \quad [21]$$

Since k_t and A_{21} are nearly constant with height while the number density of the air molecule $[M]$ acting as a collision partner falls off, the cooling rate ratio rapidly decreases with altitude. Figure 3 illustrates this situation for the CO₂ 15 μm fundamental band. Although of much smaller significance, the LTE cooling is, however, smaller in the transition region. This is due to the larger absorption of the emission coming from the adjacent warmer layers above which partially mitigates the cooling.

The bands contributing most to cooling in the infrared are, in order of importance, the CO₂ emissions at 15 μm , the O₃ bands near 9.6 μm , and the far-infrared pure rotational and 6.3 μm H₂O bands. NO 5.3 μm emission is dominant in the thermosphere, and the O(³P) 63 μm emission is also important in this region, above around 200 km. The CO₂ 15 μm and NO 5.3 μm in particular, are in non-LTE in the middle and upper atmosphere.

The effect of non-LTE on the heating is mainly through the resonant scattering of incoming solar radiation, principally in the CO₂ bands near 2.7 and 4.3 μm , and through fluorescence effects in which energy is absorbed and later reradiated, usually at a different wavelength. The CO₂ near-infrared (near-IR) bands' heating is important because it peaks at altitudes where absorption of solar radiation by O₂ and O₃ is very small.

Neglecting the CO₂ heating can lead to mean upper mesospheric temperatures about 2–8 K cooler.

The general circulation models require fast and accurate parameterizations of the cooling and heating rates, since the large computer time consumed by the full non-LTE models cannot be afforded. Several parameterizations have been developed, mainly for the Earth's and Mars' atmospheres. In these, it is common to divide the atmosphere into regions where approximations are accurate, such as the LTE region; the uppermost non-LTE region, where the cool-to-space approximation is accurate; and one or two intermediate regions, where other non-LTE approximations are made. Another factor is the number of bands contributing to the cooling. In LTE, all of them are grouped, since they have the same source function, $B(T)$. However, in the non-LTE region, each band has a different source function, usually with different transition altitudes from non-LTE to LTE. This additionally complicates the calculations in those intermediate regions, where the parameterizations are less accurate. More recently, reduced non-LTE models have been devised, limiting the inversion of the radiative transfer and statistical equilibrium equations at those intermediate regions, and they apply the LTE and cool-to-space approximations to the lowest and highest regions, respectively.

Remote Sensing of the Non-LTE Atmosphere

The first experimental studies of non-LTE in the atmosphere were made in the 1960s with infrared measurements from rocket payloads. They assumed an increased importance in the 1970s, when non-LTE radiance measurements began to be made by instruments on orbiting satellites. When the nature and the degree of the non-LTE processes affecting the observed quantity (usually thermally emitted radiance or atmospheric transmittance) are unknown, the measurements can be used to study the process in detail, and to validate theoretical models such as those described in this article. However, it is increasingly the case that the effect of non-LTE processes on the observed quantity is reasonably well understood, and the measurements are being used to determine temperature or composition. Then, the presence of non-LTE effects (even if the underlying theory is well understood) will increase the complexity of the interpretation of the data, and add an extra source of error and uncertainty. Sometimes, however, non-LTE can help by increasing the signal at high altitudes, especially when there is significant solar pumping, as is the case for CO at 4.7 μm and CO₂ at 4.3 μm , for example. The vertical coverage possible with an instrument of a given sensitivity can be greatly extended by this effect, although obviously only on the sunlit side of the planet.

Consider the radiance measured by a satellite instrument with a response function $F(\nu)$ over a finite frequency range $\Delta\nu$ at a given observation point x_{obs} . This is given for the case of limb viewing by

$$L(x_{\text{obs}}) = \int_{\Delta\nu} F(\nu) \int_{x_{\infty}}^{x_{\text{obs}}} J_{\nu}(x) \frac{d\mathcal{T}_{\nu}(x)}{dx} dx d\nu \quad [22]$$

where x is a position along the limb path line-of-sight and the integration is performed from the furthest extent of the atmosphere at the limb point, x_∞ , to the observation point at x_{obs} , passing through the tangent height of the observation point, z , and the monochromatic transmittance between x and x_{obs} is given by

$$\mathcal{T}_\nu(x, x_{\text{obs}}) = \exp\left(-\int_x^{x_{\text{obs}}} k_\nu(x') n_a(x') dx'\right) \quad [23]$$

It is useful to relate those equations to the case of LTE, which is simply done by replacing the expressions for the source function and the absorption coefficient, given by

$$\frac{J_\nu}{B_\nu} = \frac{n_2}{\bar{n}_2} \frac{k_\nu^{\text{LTE}}}{k_\nu} \quad [24]$$

and

$$\frac{k_\nu(x)}{k_\nu^{\text{LTE}}(x)} = \frac{n_1}{\bar{n}_1} \left[1 - \frac{g_1 n_2}{g_2 n_1}\right] \left[1 - \exp\left(-\frac{h\nu_0}{kT}\right)\right]^{-1} \quad [25]$$

Therefore, the emission measurements are affected by non-LTE mainly through the source function and, to a lesser extent, through the absorption coefficient (see eqns [24] and [25]). Thus, non-LTE is very important for emission measurements, particularly those measured with a limb geometry, because the relative contribution from the upper atmospheric layers, where non-LTE is more common, is larger. The non-LTE effects in nadir radiances (measured viewing near the vertical) are of less significance, since most of the radiation comes from the dense troposphere and lower stratosphere, where most emissions are in LTE. An exception is the CO_2 4.3 μm bands at daytime and NO at 5.3 μm in the thermosphere.

The effect of non-LTE on absorption spectra, where

$$L_\nu(x_{\text{obs}}) = F(\nu) L_\nu(x_\infty) \mathcal{T}_\nu(x_\infty, x_{\text{obs}}) \quad [26]$$

is much less than for emission, since it enters into the transmission function only through the absorption coefficient, and not through the source function.

In particular, non-LTE is negligible for the fundamental bands, most commonly used in absorption experiments, since the population of the ground state is not significantly affected by non-LTE (only through the vibrational partition function). Also, since most of the molecules are in the ground state at atmospheric temperatures, absorption in the hot bands (those whose lower states are not the ground state) is very weak, particularly in the tenuous upper regions where non-LTE dominates. There is, however, an important exception: the lowest vibrational level of CO_2 ($0,1^1,0$), which is responsible for the 15 μm emission. The population of this level in the atmosphere can be derived from high spectral resolution absorption measurements in the ($0,1^1,1 \leftarrow 0,1^1,0$) 4.3 μm band. From this, and using also the fundamental ($0,0,1 \leftarrow 0,0,0$) 4.3 μm band, the population of $\text{CO}_2(0,1^1,0)$, the CO_2 abundance, and the kinetic temperature (from the rotational distribution) can be retrieved simultaneously. This offers an important advantage to the analysis of emission spectra, where a simultaneous measurement of the kinetic temperature and the abundance

of the species considered in the ground and in the excited states is rarely available.

Analysis of Non-LTE Emissions

Here, we describe how atmospheric measurements have been used to improve our knowledge of non-LTE in the atmosphere. Rocket experiments in the 1970s such as the Spectral Infrared Rocket experiment (SPIRE) or the Middle Atmosphere Program/Winter in Northern Europe (MAP/WINE) campaign allowed for the first quantitative analysis of infrared non-LTE emissions (mainly in the 15 and 4.3 μm regions). Later on, instrumentation flown on the space shuttle (e.g., the Cryogenic Infrared Spectrometers and Telescopes for the Atmosphere (CRISTA) and the Cryogenic Infrared Radiance Instrumentation for Shuttle (CIRRIS)) led to important advances thanks to the increased amount of observed data. In particular, CIRRIS-1A provided valuable information on thermospheric NO emissions at 5.3 μm that allowed the study of the breakdown of rotational LTE and chemical excitations of NO due to the reaction of atomic nitrogen with molecular oxygen.

The first satellite observations of non-LTE emissions were taken by the Limb Infrared Monitor of the Stratosphere (LIMS) and the Stratospheric and Mesospheric Sounder (SAMS) on NIMBUS 7, launched in 1978. The measurements by Cryogenic Limb Array Etalon Spectrometer (CLAES) and the Improved Stratospheric and Mesospheric Sounder (ISAMS) radiometer on the Upper Atmosphere Research Satellite (UARS), taken in the 1990s, showed systematic day–night differences in several infrared channels that are attributable to non-LTE effects. For example, the daytime signal of the ISAMS 6.3 μm band of water vapor at 70 km observed at high effective spectral resolution is 2–3 times larger than that at nighttime; this factor is too large to be accounted for by any reasonable change in the concentration of water vapor. CLAES provided experimental evidence for the excitation of the CO_2 ν_3 mode by energy transfer from electronically excited $\text{O}(^1D)$ through $\text{N}_2(1)$.

The Michelson Interferometer for Passive Atmospheric Sounding (MIPAS) on Envisat, operating during 2002–12, was a very suitable instrument for studying atmospheric non-LTE emissions because of its wide spectral coverage, allowing for measuring emissions from a given compound in different spectral regions; its high spectral resolution, enabling the discrimination of emissions from different species and between different bands of the same species; and its high sensitivity, allowing measurement of the emission in the upper atmosphere where non-LTE emissions are most important. All this has led MIPAS to provide us with significant improvements in our knowledge of the non-LTE atmospheric infrared emissions of many species such as H_2O , CH_4 , CO_2 , O_3 , NO_2 , NO , and N_2O . For example, MIPAS has provided the first evidence of $\text{CH}_4(\nu_4)$ non-LTE emissions in the mesosphere. Its high spectral resolution has also allowed researchers to derive new collisional rates between the CO_2 02^01 , 02^21 , and 10^01 states that emit the 4.3 μm second hot bands (see Figure 4).

MIPAS has taken the most unequivocal spectra of H_2O in the mesosphere, clearly demonstrating the distinct non-LTE daytime emissions from the fundamental and hot bands at 6.3 μm . Furthermore, it has provided the most accurate

Figure 4 High-resolution limb spectra of the Earth's atmosphere near $4.3\ \mu\text{m}$ at a tangent height of 70 km. The upper panel shows the spectrum taken by MIPAS on 1 January 2009 at (24° S , 60° E) and a solar zenith angle of 62.7° . The lower panel shows the residuals (the residuals are the differences of the MIPAS measurements – the calculations) for two non-LTE simulations performed with the 'standard' collisional rates for CO_2 (red) and those derived to fit the measured spectra (blue).

collisional rate for the relaxation of $\text{H}_2\text{O}(020)$ by O_2 . In addition, MIPAS has given the first experimental confirmation of the non-LTE processes exciting the $\text{NO}(1)$ level, emitting near $5.3\ \mu\text{m}$, in the daytime stratosphere. Measurements of the NO rotational and spin transitions in the $5.3\ \mu\text{m}$ emission in the thermosphere, both under quiescent and geomagnetically perturbed conditions, have confirmed theoretical calculations of NO rotational and spin non-LTE populations. MIPAS has also made it possible to throw light on the puzzle about whether or not the $\text{NO}_2(\nu_3)$ levels are non-LTE excited in the daytime stratosphere. A recent analysis has shown that the photochemical excitation of $\text{NO}_2(\nu_3 = 1-4)$ levels is a factor of 50 smaller than previously thought, leading to small non-LTE deviations for these levels. Finally, measurements of the non-LTE emissions of the carbon monoxide first hot band, $\text{CO}(2-1)$, near $4.7\ \mu\text{m}$ and of $\text{N}_2\text{O}(001)$ near $4.5\ \mu\text{m}$ have also been observed by MIPAS for the first time.

The still-operational Sounding of the Atmosphere Using Broadband Emission Radiometry (SABER) experiment on the NASA TIMED mission has allowed researchers to constrain the $\text{OH}-\text{N}_2-\text{CO}_2$ vibration-vibration energy transfer, an important driver of the nighttime non-LTE enhancement of CO_2 $4.3\ \mu\text{m}$ emissions, thanks to its simultaneous observation of CO_2 and OH emissions at $4.3\ \mu\text{m}$ and $1.6-2.0\ \mu\text{m}$, respectively.

As mentioned in this article, most of the measurements used to study non-LTE have been taken in emission. An exception is the use of solar occultation spectroscopy by the Atmospheric Trace Molecule Spectroscopy (ATMOS) spectrometer to study the non-LTE population of $\text{CO}_2(0,1^1,0)$.

Non-LTE Retrievals

The improved knowledge of non-LTE processes gained from experimental studies in conjunction with the rapidly growing computing power of modern data-processing facilities are the key for the operational retrieval of temperature and atmospheric composition from space-borne non-LTE emission measurements, and hence for the extension of the remotely

sounded altitude region toward the mesosphere and lower thermosphere. Non-LTE retrieval algorithms require the expensive computation of the non-LTE populations of the sounded infrared emitters under the actual atmospheric conditions. Since the populations typically depend on the retrieval parameters (temperature or composition), these computations have to be repeated in each step of the iterative inversion procedure.

Non-LTE retrieval schemes have been successfully applied to the data processing of space-borne atmospheric remote sensing experiments such as ISAMS on UARS, the CRISTA experiment flown on the space shuttle, and the recent MIPAS-Envisat and SABER-TIMED instruments. These non-LTE measurements have greatly improved our knowledge of the temperature structure and distributions of CO , CO_2 , O_3 , H_2O , OH , NO , and NO_2 in the middle and upper atmosphere. Figure 5 shows some examples of quantities retrieved under non-LTE from MIPAS spectra.

Non-LTE in Planetary Atmospheres

Non-LTE situations are not limited to the Earth's atmosphere. The atmospheres of the other terrestrial planets, Mars and Venus, consist of nearly pure carbon dioxide, making the study of non-LTE processes in that molecule of crucial importance for understanding the thermal structure of their upper atmospheres. Also, the different physical and chemical conditions in these atmospheres relative to the Earth offer scenarios where different combinations of processes may be at work, and comparison with the terrestrial case can provide deeper insights into the non-LTE problem. For example, the weak hot and isotopic bands of CO_2 are much more important for radiative cooling in the Venusian atmosphere than on the Earth, and LTE applies up to much higher altitudes in the $15\ \mu\text{m}$ bands. The larger concentration of CO_2 means that these bands are optically thicker at a given pressure level, less radiative energy is lost, and a slower thermal collisional rate is enough to keep their populations in LTE. Another interesting example is the

Figure 5 Monthly zonal mean of temperature, O₃, H₂O, and CO volume-mixing ratios (VMRs) in the middle atmosphere, as well as daytime temperature and NO VMR in the thermosphere retrieved considering non-LTE from MIPAS spectra taken on July 2009.

appearance of the natural laser emission in the 10 μm bands of CO_2 in the Martian atmosphere, which is absent on Earth because of the lower relative abundance of CO_2 , and is weak in Venus because of its warmer atmosphere.

Differences in the compositions of the terrestrial planet atmospheres are important in other ways. The major atmospheric constituent on Earth, N_2 , acts as an intermediary through its first vibrationally excited state to redistribute the energy of CO_2 ν_3 levels excited by absorption of solar radiation. The second most abundant species, O_2 , plays a similar role for distributing the vibrational energy of water vapor and methane. On Mars and Venus, it is the CO_2 itself that, through much faster near-resonant vibrational–vibrational energy exchange, distributes the absorbed solar energy internally and makes efficient thermal cooling possible at 15 μm . All studies of the cooling and heating rates in the Venusian and Martian atmospheres have stressed the important role of atomic oxygen: the thermal collisions between CO_2 and $\text{O}(^3\text{P})$ are crucial for the cooling of the upper regions of a CO_2 atmosphere.

For Venus and Mars, only a few measurements were available until the beginning of the twenty-first century. A limited amount of spectra were taken on the dayside limb of Venus by NIMS–Galileo during its fast flyby of Venus in 1991. Recently, however, the PFS and OMEGA instruments on Mars Express, launched in 2003, and especially VIRTIS on Venus Express, launched in 2005 (see Figure 6), are supplying the first systematic sounding (nadir and limb) of these atmospheres in the mid-infrared (mid-IR).

The atmospheres of the giant planets and some of their satellites, especially Titan, contain radiatively active gases such as methane, hydrogen cyanide, carbon monoxide, and various other hydrocarbons. These gases play an important role in the thermal balance of their upper atmospheres, analogous to that of CO_2 on Earth. Thus, non-LTE models for planetary atmospheres other than Earth were originally developed to study energy balance problems. During the last decade, however, the availability of the European Space Agency's Infrared Space Observatory–Short Wavelength Spectrometer (ISO–SWS) observations, the high spectral resolution ground-based measurements in the near-IR, and the measurements of the Visible and Infrared Mapping Spectrometer (VIMS) instrument onboard Cassini have triggered modeling efforts for deriving temperature and composition from these atmospheres. That includes non-LTE modeling for the vibrational levels of CH_4 , CO , HCN , C_2H_2 , C_2H_6 , CH_3D , PH_3 , and NH_3 in the mid- and near-IR.

In the very tenuous atmospheres, consisting of water vapor, carbon monoxide, methane, and other gases, which make up the comae of comets, the pressures are so low that LTE never applies anywhere. In this case, not only vibrational but also rotational non-LTE have to be considered in the analysis of composition measurements, even those made in the microwave part of the spectrum.

Synopsis

Sunlight illuminating the Earth's atmosphere is scattered by gas molecules and suspended particles, giving rise to blue skies, white clouds, and optical displays such as rainbows and halos. By scattering and absorbing the shortwave solar radiation and the longwave radiation emitted by the underlying surface, cloud and aerosol particles strongly affect the radiation budget of the terrestrial climate system. As a consequence of the dependence of scattering characteristics on particle size, morphology, and composition, scattered light can be remarkably rich in information on particle properties and thus provides a sensitive tool for remote retrievals of macro- and microphysical parameters of clouds and aerosols.

Introduction

A parallel beam of light, or of any electromagnetic radiation, propagates in a vacuum without a change in its characteristics. However, interposing a particle into the beam causes two fundamental effects. First, the particle may convert some of the energy contained in the electromagnetic field into other forms of energy such as heat. This phenomenon is called absorption. Second, the directional propagation of electromagnetic energy and its polarization state get modified. This phenomenon is called scattering.

The scattering and absorption characteristics of an isolated particle are often complex functions of the particle's size, morphology, and composition. They can be determined by obtaining a numerically exact solution of the Maxwell equations or by using a suitable experimental technique. Direct computer solutions of the Maxwell equations become much more involved and are often impracticable for a compound object in the form of a cloud of particles. In such cases, one has to use a physically based asymptotic solution of the Maxwell equations called the radiative transfer equation (RTE).

Sunlight incident on the Earth's atmosphere is scattered by gas molecules and suspended particles, giving rise to blue skies, white clouds, and various optical displays such as rainbows, halos, and the glory. By scattering and absorbing the shortwave solar radiation and the longwave radiation emitted by the underlying surface, cloud and aerosol particles strongly affect the radiation budget of the terrestrial climate system. As a consequence of the dependence of scattering characteristics on particle size, morphology, and composition, scattered light can be remarkably rich in implicit information on particle properties and thus provides a sensitive tool for remote retrievals of macro- and microphysical parameters of clouds and aerosols.

Electromagnetic Scattering by a Fixed Particle

To explain the fundamental concept of electromagnetic scattering by a fixed particle, let us assume that the electromagnetic field is time harmonic, which allows one to fully describe it at any moment in time everywhere in space as the solution of the frequency-domain Maxwell equations. Specifically, it is convenient to factor out the time-harmonic dependence of the

complex electric and magnetic fields: $\mathbf{E}(\mathbf{r}, t) = \exp(-i\omega t) \mathbf{E}(\mathbf{r})$ and $\mathbf{H}(\mathbf{r}, t) = \exp(-i\omega t) \mathbf{H}(\mathbf{r})$, where $\mathbf{r}$ is the position vector of the observation point, t is time, ω is the angular frequency, and $i = (-1)^{1/2}$. The actual electric and magnetic fields are obtained by taking the real part of the respective complex fields. The field amplitudes $\mathbf{E}(\mathbf{r})$ and $\mathbf{H}(\mathbf{r})$ can be found from the following curl equations:

$$\left. \begin{aligned} \nabla \times \mathbf{E}(\mathbf{r}) &= i\omega\mu_0 \mathbf{H}(\mathbf{r}) \\ \nabla \times \mathbf{H}(\mathbf{r}) &= -i\omega\epsilon_1 \mathbf{E}(\mathbf{r}) \end{aligned} \right\} \text{inside } V_{\text{EXT}}, \quad [1]$$

$$\left. \begin{aligned} \nabla \times \mathbf{E}(\mathbf{r}) &= i\omega\mu_0 \mathbf{H}(\mathbf{r}) \\ \nabla \times \mathbf{H}(\mathbf{r}) &= -i\omega\epsilon_2(\mathbf{r}, \omega) \mathbf{E}(\mathbf{r}) \end{aligned} \right\} \text{inside } V_{\text{INT}}. \quad [2]$$

Here, V_{INT} is the cumulative 'interior' volume occupied by the scattering particle; V_{EXT} is the infinite exterior region, which is assumed to be homogeneous, linear, isotropic, and non-absorbing; the host medium and the particle are assumed to be nonmagnetic; μ_0 is the permeability of a vacuum; ϵ_1 is the real-valued electric permittivity of the host medium; and $\epsilon_2(\mathbf{r}, \omega)$ is the complex permittivity of the particle. Since the first relations in eqns [1] and [2] yield the magnetic field provided that the electric field is known everywhere, the solution of the Maxwell equations is usually sought in terms of only the electric field. To have a unique solution, eqns [1] and [2] must be supplemented by appropriate boundary conditions at the particle surface as well as by the so-called radiation conditions at infinity.

Note that although the amplitudes $\mathbf{E}(\mathbf{r})$ and $\mathbf{H}(\mathbf{r})$ do not depend on time explicitly, they can fluctuate randomly if the electromagnetic field is quasimonochromatic. However, such fluctuations are assumed to occur much more slowly than the time-harmonic oscillations described by the factor $\exp(-i\omega t)$, which justifies the use of the frequency-domain Maxwell equations at any given moment.

Let us now assume that in the absence of the particle, the electromagnetic field is given by the simplest solution of the Maxwell equations in the form of a plane electromagnetic wave propagating in the direction of the wave vector $\mathbf{k}^{\text{inc}}$:

$$\mathbf{E}^{\text{inc}}(\mathbf{r}) = \mathbf{E}_0^{\text{inc}} \exp(i\mathbf{k}^{\text{inc}} \cdot \mathbf{r}) \text{ everywhere in space.} \quad [3]$$

As shown schematically in Figure 1(a), eqn [3] represents the transport of electromagnetic energy from one point to another in the absence of the particle and embodies the concept of

Figure 1 Electromagnetic scattering by a fixed particle. In this case, the particle is an aggregate consisting of three monomers in contact.

a perfectly monochromatic parallel beam of light. The presence of the particle modifies the electromagnetic field that would exist otherwise. It is this modification that is called *electromagnetic scattering*.

It is customary to call the difference between the total field in the presence of the particle (i.e., $E(\mathbf{r})$) and the original field that would exist in the absence of the object (i.e., $E^{\text{inc}}(\mathbf{r})$) the ‘scattered field’ and denote it as $E^{\text{sca}}(\mathbf{r})$ (see **Figure 1(b)**). Thus, the total field in the presence of the particle is intentionally represented as the sum of the respective incident (original) and scattered fields:

$$E(\mathbf{r}) = E^{\text{inc}}(\mathbf{r}) + E^{\text{sca}}(\mathbf{r}). \quad [4]$$

Of course, one can think of incident fields other than a plane wave and thereby generalize the concept of scattering. In this regard, an especially convenient framework is provided by the so-called volume integral equation which follows from the Maxwell equations and incorporates the boundary and radiation conditions:

$$E(\mathbf{r}) = E^{\text{inc}}(\mathbf{r}) + k^2 \int_{V_{\text{INT}}} d\mathbf{r}' \vec{G}(\mathbf{r}, \mathbf{r}') \cdot E(\mathbf{r}') [m^2(\mathbf{r}') - 1], \quad [5]$$

where $m(\mathbf{r}') = [\epsilon_2(\mathbf{r}', \omega)/\epsilon_1]^{1/2}$ is the refractive index of the interior relative to that of the host exterior medium; $k = |\mathbf{k}^{\text{inc}}| = \omega(\epsilon_1 \mu_0)^{1/2} = 2\pi/\lambda$ is the wave number; λ is the wavelength; $\vec{G}(\mathbf{r}, \mathbf{r}')$ is the free-space dyadic Green’s function; and $E^{\text{inc}}(\mathbf{r})$ is any physically realizable solution of the Maxwell equations for an infinite homogeneous medium. One can see that eqn [5] expresses the total field everywhere in space in terms of the total internal field. The latter is not known in general and must be found by solving eqn [5] either analytically or numerically.

Far-Field Scattering

Equation [5] can be used to show that at a distance from the particle greatly exceeding its size, in the so-called far zone, the scattered field becomes an outgoing spherical wave (**Figure 1(b)**). By placing the origin O of the spherical

Figure 2 Scattering in the far zone of the particle.

coordinate system at the geometrical center of the particle (**Figure 2**), we have:

$$E^{\text{sca}}(\mathbf{r}) \xrightarrow{r \rightarrow \infty} \frac{\exp(ikr)}{r} E_1^{\text{sca}}(\hat{\mathbf{n}}^{\text{sca}}), \quad [6]$$

where $r = |\mathbf{r}|$ is the distance from the origin, $\hat{\mathbf{n}}^{\text{inc}} = \mathbf{k}^{\text{inc}}/k$ is a unit vector in the incidence direction, and $\hat{\mathbf{n}}^{\text{sca}} = \mathbf{r}/r$ is a unit vector in the scattering direction.

The electric and magnetic field vectors of the scattered spherical wave are perpendicular to the scattering direction, while those of the incident plane wave are normal to the incidence direction. It is therefore convenient to denote by $\mathbf{E}$ a two-element column formed by the θ - and φ -components of either electric field vector:

$$\mathbf{E} = \begin{bmatrix} E_\theta \\ E_\varphi \end{bmatrix}. \quad [7]$$

As usual, the polar (zenith) angle $0 \leq \theta \leq \pi$ is measured from the positive z -axis, while the azimuth angle $0 \leq \varphi < \pi$ is measured from the positive x -axis in the clockwise direction when looking in the direction of the positive z -axis. The use of this notation allows us to write the scattered field as:

$$E^{\text{sca}}(r\hat{\mathbf{n}}^{\text{sca}}) = \frac{\exp(ikr)}{r} \mathbf{S}(\hat{\mathbf{n}}^{\text{sca}}, \hat{\mathbf{n}}^{\text{inc}}) \mathbf{E}_0^{\text{inc}}, \quad [8]$$

where $\mathbf{S}$ is the 2×2 so-called amplitude scattering matrix expressing the θ - and φ -components of the scattered spherical wave in those of the incident plane wave. This relation plays a key role in the theory of electromagnetic scattering.

Optical Observables

The typically high frequency of time-harmonic electromagnetic oscillations makes it virtually impossible to measure the electric and magnetic fields associated with the incident and scattered waves using traditional optical instruments. Therefore, in order to make the theory applicable to analyses of actual observations, the scattering phenomenon must be characterized in terms of derivative quantities that can be measured directly (i.e., optical *observables*). The conventional approach to

address this problem is to use four real-valued quantities I , Q , U , and V , which have the dimension of monochromatic energy flux (Wm^{-2}) and fully characterize a transverse electromagnetic wave inasmuch as it is subject to practical optical analysis. These quantities, called the Stokes parameters, are always defined with respect to a plane containing the direction of wave propagation, form the four-element Stokes column vector $\mathbf{I}$, and carry information about both the total intensity I and the polarization state of the wave. The Stokes parameters are intentionally defined such that the rapidly oscillating time-harmonic factor $\exp(-i\omega t)$ vanishes upon multiplication by its complex-conjugate counterpart: $\exp(-i\omega t)[\exp(-i\omega t)]^* \equiv 1$, where the asterisk denotes complex conjugation.

In the case of scattering in the far zone, both the incident plane wave and the outgoing scattered spherical wave are transverse. This allows one to define the corresponding sets of Stokes parameters:

$$\mathbf{I}^{\text{inc}} = \begin{bmatrix} I^{\text{inc}} \\ Q^{\text{inc}} \\ U^{\text{inc}} \\ V^{\text{inc}} \end{bmatrix} = \frac{1}{2} \sqrt{\frac{\epsilon_1}{\mu_0}} \begin{bmatrix} E_{0\theta}^{\text{inc}} (E_{0\theta}^{\text{inc}})^* + E_{0\phi}^{\text{inc}} (E_{0\phi}^{\text{inc}})^* \\ E_{0\theta}^{\text{inc}} (E_{0\theta}^{\text{inc}})^* - E_{0\phi}^{\text{inc}} (E_{0\phi}^{\text{inc}})^* \\ -E_{0\theta}^{\text{inc}} (E_{0\phi}^{\text{inc}})^* - E_{0\phi}^{\text{inc}} (E_{0\theta}^{\text{inc}})^* \\ i [E_{0\phi}^{\text{inc}} (E_{0\theta}^{\text{inc}})^* - E_{0\theta}^{\text{inc}} (E_{0\phi}^{\text{inc}})^*] \end{bmatrix}, \quad [9]$$

$$\mathbf{I}^{\text{sca}}(r\hat{\mathbf{n}}^{\text{sca}}) = \begin{bmatrix} I^{\text{sca}} \\ Q^{\text{sca}} \\ U^{\text{sca}} \\ V^{\text{sca}} \end{bmatrix} = \frac{1}{r^2} \frac{1}{2} \sqrt{\frac{\epsilon_1}{\mu_0}} \begin{bmatrix} E_{1\theta}^{\text{sca}} (E_{1\theta}^{\text{sca}})^* + E_{1\phi}^{\text{sca}} (E_{1\phi}^{\text{sca}})^* \\ E_{1\theta}^{\text{sca}} (E_{1\theta}^{\text{sca}})^* - E_{1\phi}^{\text{sca}} (E_{1\phi}^{\text{sca}})^* \\ -E_{1\theta}^{\text{sca}} (E_{1\phi}^{\text{sca}})^* - E_{1\phi}^{\text{sca}} (E_{1\theta}^{\text{sca}})^* \\ i [E_{1\phi}^{\text{sca}} (E_{1\theta}^{\text{sca}})^* - E_{1\theta}^{\text{sca}} (E_{1\phi}^{\text{sca}})^*] \end{bmatrix}. \quad [10]$$

Then the responses of well-collimated polarization-sensitive radiometers located in the far zone of the particle can be described in terms of the 4×4 phase and extinction matrices as follows.

In the absence of the particle (Figure 3(a)), radiometer 2 registers no signal, whereas radiometer 1 reacts to the incident plane wave:

$$\text{Signal 1} = \Delta S \mathbf{I}^{\text{inc}}, \quad [11]$$

$$\text{Signal 2} = 0, \quad [12]$$

where ΔS is the area of the objective lens. In the presence of the particle (Figure 3(b)), radiometer 2 reacts only to the scattered spherical wave, and its polarized reading is fully characterized by the product of the phase matrix $\mathbf{Z}$ and the Stokes column vector of the incident wave:

$$\begin{aligned} \text{Signal 2} &= \Delta S \mathbf{I}^{\text{sca}}(r\hat{\mathbf{n}}^{\text{sca}}) \\ &= \frac{\Delta S}{r^2} \mathbf{Z}(\hat{\mathbf{n}}^{\text{sca}}, \hat{\mathbf{n}}^{\text{inc}}) \mathbf{I}^{\text{inc}}, \quad \hat{\mathbf{n}}^{\text{sca}} \neq \hat{\mathbf{n}}^{\text{inc}}. \end{aligned} \quad [13]$$

The elements of the phase matrix have the dimension of area and are quadratic combinations of the elements of the

Figure 3 The readings of well-collimated polarization-sensitive radiometers in the presence of the particle differ from those in the absence of the particle.

amplitude scattering matrix $\mathbf{S}(\hat{\mathbf{n}}^{\text{sca}}, \hat{\mathbf{n}}^{\text{inc}})$. One can see that, in general, the phase matrix relates the Stokes parameters of the incident and scattered waves defined with respect to different reference planes: the meridional plane of the incidence direction $\hat{\mathbf{n}}^{\text{inc}}$ and that of the scattering direction $\hat{\mathbf{n}}^{\text{sca}}$, respectively.

Unlike radiometer 2, radiometer 1 in Figure 3(b) is facing the incident light, and, accordingly, its polarized reading consists of three parts:

1. the one due to the incident wave;
2. the one due to the forward-scattered wave; and
3. the one due to the interference of the incident wave and the wave scattered by the object in the exact forward direction:

$$\text{Signal 1} = \Delta S \mathbf{I}^{\text{inc}} + \frac{\Delta S}{r^2} \mathbf{Z}(\hat{\mathbf{n}}^{\text{inc}}, \hat{\mathbf{n}}^{\text{inc}}) \mathbf{I}^{\text{inc}} - \mathbf{K}(\hat{\mathbf{n}}^{\text{inc}}) \mathbf{I}^{\text{inc}}. \quad [14]$$

The third part is described by minus the product of the extinction matrix $\mathbf{K}$ and the Stokes column vector of the incident wave. The elements of the extinction matrix also have the dimension of area and are linear combinations of the elements of the forward-scattering amplitude matrix $\mathbf{S}(\hat{\mathbf{n}}^{\text{inc}}, \hat{\mathbf{n}}^{\text{inc}})$. Placing radiometer 1 sufficiently far from the particle makes the second term on the right-hand side of eqn [14] negligibly small.

In many respects, the measurement situation depicted in Figures 3(a) and 3(b) embodies the concept of electromagnetic scattering. Indeed, it demonstrates that in the absence of the particle, radiometer 2 would measure no signal, while the

signal measured by radiometer 1 allows one to measure the Stokes vector of the incident wave $\mathbf{I}^{\text{inc}}$. In the presence of the particle, the readings of both radiometers change. The reading of radiometer 2 is now proportional to the Stokes column vector of the scattered spherical wave, while the polarization signal measured by radiometer 1 is modified in two ways. First, the total measured electromagnetic power is attenuated as a combined result of the scattering of electromagnetic energy by the object in all directions and, possibly, the transformation of electromagnetic energy into other forms of energy (such as heat) inside the object. Second, the attenuation rates for the four Stokes components of the measured signal can, in general, be different. The latter effect is typical of objects lacking perfect spherical symmetry and is called dichroism.

Thus, to describe far-field scattering means, in effect, to quantify the differences between the readings of radiometers 1 and 2 in the presence of the object and in the absence of the object. This quantification can be fully achieved in terms of the phase and extinction matrices, which depend on object characteristics such as size, shape, refractive index, and orientation. Both matrices can be readily computed provided that the amplitude scattering matrix is already known.

In the case of quasimonochromatic fields, eqns [11]–[14] remain valid provided that now the Stokes column vectors of the incident and scattered fields are defined as averages of the right-hand sides of eqns [9] and [10] over a time interval much longer than the typical period of random fluctuations.

Derivative Quantities

There are several derivative quantities that are often used to describe various observable manifestations of electromagnetic scattering. The product of the extinction cross-section multiplied by the intensity of the incident plane wave yields the total attenuation of the electromagnetic power measured by radiometer 1 in Figure 3(b) owing to the presence of the particle. This means that the extinction cross-section depends, in general, on the polarization state and propagation direction of the incident wave and is given by:

$$C_{\text{ext}}(\hat{\mathbf{n}}^{\text{inc}}) = \frac{1}{I^{\text{inc}}} [K_{11}(\hat{\mathbf{n}}^{\text{inc}})I^{\text{inc}} + K_{12}(\hat{\mathbf{n}}^{\text{inc}})Q^{\text{inc}} + K_{13}(\hat{\mathbf{n}}^{\text{inc}})U^{\text{inc}} + K_{14}(\hat{\mathbf{n}}^{\text{inc}})V^{\text{inc}}]. \quad [15]$$

The product of the scattering cross-section multiplied by the intensity of the incident plane wave yields the total far-field power of the scattered wave:

$$C_{\text{sca}}(\hat{\mathbf{n}}^{\text{inc}}) = \frac{1}{I^{\text{inc}}} \int_{4\pi} d\hat{\mathbf{n}}^{\text{sca}} [Z_{11}(\hat{\mathbf{n}}^{\text{sca}}, \hat{\mathbf{n}}^{\text{inc}})I^{\text{inc}} + Z_{12}(\hat{\mathbf{n}}^{\text{sca}}, \hat{\mathbf{n}}^{\text{inc}})Q^{\text{inc}} + Z_{13}(\hat{\mathbf{n}}^{\text{sca}}, \hat{\mathbf{n}}^{\text{inc}})U^{\text{inc}} + Z_{14}(\hat{\mathbf{n}}^{\text{sca}}, \hat{\mathbf{n}}^{\text{inc}})V^{\text{inc}}]. \quad [16]$$

This implies that C_{sca} also depends on the polarization state as well as on the propagation direction of the incident wave. The absorption cross-section is defined as the difference between the extinction and scattering cross-sections:

$$C_{\text{abs}}(\hat{\mathbf{n}}^{\text{inc}}) = C_{\text{ext}}(\hat{\mathbf{n}}^{\text{inc}}) - C_{\text{sca}}(\hat{\mathbf{n}}^{\text{inc}}) \geq 0. \quad [17]$$

All optical cross-sections have the dimension of area. Finally, the dimensionless single-scattering albedo is defined as the ratio of the scattering and extinction cross-sections:

$$\tilde{\omega}(\hat{\mathbf{n}}^{\text{inc}}) = \frac{C_{\text{sca}}(\hat{\mathbf{n}}^{\text{inc}})}{C_{\text{ext}}(\hat{\mathbf{n}}^{\text{inc}})} \leq 1. \quad [18]$$

An important particular case of the phase matrix is the scattering matrix, defined by:

$$\mathbf{F}(\Theta) = \mathbf{Z}(\theta^{\text{sca}} = \Theta, \varphi^{\text{sca}} = 0; \theta^{\text{inc}} = 0, \varphi^{\text{inc}} = 0), \quad 0 \leq \Theta < \pi, \quad [19]$$

where Θ , traditionally called the scattering angle, is the angle between the incidence and scattering directions. It is easy to see that the scattering matrix relates the Stokes parameters of the incident and scattered waves defined with respect to the same so-called scattering plane (i.e., the plane through the incidence and scattering directions).

Scattering by a Random Many-Particle Group

Although we have been so far discussing electromagnetic scattering by a ‘single particle,’ the concept of electromagnetic scattering and eqns [1]–[5] remain valid irrespective of the specific morphology of the scattering object. In particular, they are valid for what a human eye could classify as a ‘collection of discrete particles.’ Examples of such ‘many-particle’ objects are clouds, particulate surfaces, and particle suspensions. In all such cases, the electromagnetic field perceives a morphologically complex ‘many-particle’ object at any moment in time as one scatterer in the form of a specific spatial distribution of the relative refractive index throughout the cumulative interior volume V_{INT} in eqns [2] and [5].

However, the numerically exact computer solution of the Maxwell equations becomes prohibitively expensive when the size parameter of the object (i.e., the product of the wave number k and the radius of the smallest circumscribing sphere of the object) exceeds ~ 100 . Furthermore, the concept of far-field scattering is inapplicable in the majority of practical situations involving very large many-particle groups such as clouds. Indeed, radiometers are often positioned inside or relatively close to the cloud (Figure 4) (i.e., in its near zone). As a consequence, one has to resort to an approximate computational technique and often abandon the attractively simple formulas of far-field scattering.

Two conventional approaches widely used to treat electromagnetic scattering by random particle groups are the single-scattering approximation (SSA) and the radiative transfer theory (RTT). The SSA is applicable to a relatively small, ‘optically tenuous’ group of N particles viewed from a distance much greater than the entire size of the group. In this case, eqns [11]–[14] remain valid provided that (1) the scattering signal is accumulated over a time interval long enough to establish full statistical randomness of the group; and (2) the phase, extinction, and scattering matrices of the entire group are also averaged over time. Then:

$$\langle \mathbf{Z}(\hat{\mathbf{n}}^{\text{sca}}, \hat{\mathbf{n}}^{\text{inc}}) \rangle_t = N \langle \mathbf{Z}(\hat{\mathbf{n}}^{\text{sca}}, \hat{\mathbf{n}}^{\text{inc}}) \rangle_{\xi}, \quad [20]$$

Figure 4 A well-collimated polarization-sensitive radiometer is placed inside a cloud of particles.

$$\langle \mathbf{K}(\hat{\mathbf{n}}^{\text{inc}}) \rangle_t = N \langle \mathbf{K}(\hat{\mathbf{n}}^{\text{inc}}) \rangle_\xi, \quad [21]$$

$$\langle \mathbf{F}(\Theta) \rangle_t = N \langle \mathbf{F}(\Theta) \rangle_\xi, \quad [22]$$

where $\langle \mathbf{Z}(\hat{\mathbf{n}}^{\text{sca}}, \hat{\mathbf{n}}^{\text{inc}}) \rangle_\xi$, $\langle \mathbf{K}(\hat{\mathbf{n}}^{\text{inc}}) \rangle_\xi$, and $\langle \mathbf{F}(\Theta) \rangle_\xi$ are the *single-particle* phase, extinction, and scattering matrix, respectively, averaged over all physically realizable particle states ξ in the group. The state of a particle indicates collectively its size, refractive index, shape, and orientation (i.e., all physical characteristics except the position). Note that it is the assumption of full ergodicity of the random scattering process that allows one to replace time averaging by ensemble averaging in eqns [20]–[22]. Obviously, the time averages of the extinction, scattering, and absorption cross-sections of the entire random particle group can be expressed similarly in terms of the respective ensemble-averaged single-particle cross-sections. The single-scattering albedo of the group is then given by:

$$\tilde{\omega}(\hat{\mathbf{n}}^{\text{inc}}) = \frac{\langle C_{\text{sca}}(\hat{\mathbf{n}}^{\text{inc}}) \rangle_\xi}{\langle C_{\text{ext}}(\hat{\mathbf{n}}^{\text{inc}}) \rangle_\xi}. \quad [23]$$

The RTT is an expressly near-field theory that has recently been derived directly from the Maxwell equations and allows one to model the response of a well-collimated radiometer located inside or relatively close to a random multiparticle scattering object (Figure 4). Among the conditions of applicability of the RTE are the asymptotic requirement $N \rightarrow \infty$; the ‘low-density’ requirement, according to which every particle must be located sufficiently far from all the other particles; and the assumption that the scattering signal is accumulated over a time interval long enough to establish full ergodicity of the random scattering process. The integro-differential form of the RTE reads:

$$\hat{\mathbf{q}} \cdot \nabla \tilde{\mathbf{I}}(\mathbf{r}, \hat{\mathbf{q}}) = -n_0 \langle \mathbf{K}(\hat{\mathbf{q}}) \rangle_\xi \tilde{\mathbf{I}}(\mathbf{r}, \hat{\mathbf{q}}) + n_0 \int_{4\pi} d\hat{\mathbf{q}}' \langle \mathbf{Z}(\hat{\mathbf{q}}, \hat{\mathbf{q}}') \rangle_\xi \tilde{\mathbf{I}}(\mathbf{r}, \hat{\mathbf{q}}'), \quad [24]$$

where n_0 is the average particle number density, $d\hat{\mathbf{q}}'$ is an elementary solid angle centered on the unit vector $\hat{\mathbf{q}}'$, and $\tilde{\mathbf{I}}(\mathbf{r}, \hat{\mathbf{q}})$ is the four-component so-called specific Stokes column vector. Unlike the Stokes column vectors [9] and [10], $\tilde{\mathbf{I}}(\mathbf{r}, \hat{\mathbf{q}})$ has the dimension of radiance ($\text{Wm}^{-2} \text{sr}^{-1}$). Thus, knowledge of the ensemble-averaged single-particle phase and extinction matrices is also required in order to solve the RTE.

The fundamental importance of the RTT is that its solution, $\tilde{\mathbf{I}}(\mathbf{r}, \hat{\mathbf{q}})$, directly quantifies the response of a well-collimated polarization-sensitive radiometer oriented along the unit vector $\hat{\mathbf{q}}$ at the observation point $\mathbf{r}$ (Figure 4). Furthermore, the integral $\int_{4\pi} d\hat{\mathbf{q}} \hat{\mathbf{q}} \tilde{\mathbf{I}}(\mathbf{r}, \hat{\mathbf{q}})$ gives the time-averaged Poynting vector describing the direction and rate of the local electromagnetic energy transport. Thus, the RTT is directly applicable to solving both remote-sensing and radiation budget problems.

Symmetries

In general, all elements of the extinction and phase matrices entering eqns [13] and [14] can be nonzero, which implies that the intensity I registered by radiometers 1 and 2 in Figure 3(b) can depend on all four Stokes parameters of the incident field rather than only on its intensity. This fact emphasizes the vectorial (rather than scalar) character of electromagnetic scattering. In particular, dichroism results in different attenuation rates for different polarization components of the incident field. This causes, for example, depolarization of radar signals propagating through precipitation. The scattered wave recorded by radiometer 2 in Figure 3(b) also has polarization characteristics different from those of the incident field, thereby making polarimetry a sensitive particle characterization technique.

In many cases of practical interest, the mathematical structure of the ensemble-averaged extinction, phase, and scattering matrices becomes much simpler. This happens, for example, when (1) the distribution of particle orientations in a random group during the measurement is uniform, and (2) each particle in the group has a plane of symmetry and/or is accompanied by its mirror counterpart. Then the average extinction, scattering, and absorption cross-sections and the single-scattering albedo become independent of the direction of propagation and polarization state of the incident field. The average extinction matrix is diagonal and given by:

$$\langle \mathbf{K}(\hat{\mathbf{n}}^{\text{inc}}) \rangle_\xi \equiv \langle \mathbf{K} \rangle_\xi = \langle C_{\text{ext}} \rangle_\xi \text{diag}[1, 1, 1, 1]. \quad [25]$$

The average phase matrix satisfies certain useful symmetry relations and depends on only the difference between the azimuthal angles of the scattering and incidence directions rather than on their specific values. The average scattering matrix has a simple block-diagonal structure with only six independent elements:

$$\langle \mathbf{F}(\Theta) \rangle_\xi = \begin{bmatrix} \langle F_{11}(\Theta) \rangle_\xi & \langle F_{12}(\Theta) \rangle_\xi & 0 & 0 \\ \langle F_{12}(\Theta) \rangle_\xi & \langle F_{22}(\Theta) \rangle_\xi & 0 & 0 \\ 0 & 0 & \langle F_{33}(\Theta) \rangle_\xi & \langle F_{34}(\Theta) \rangle_\xi \\ 0 & 0 & -\langle F_{34}(\Theta) \rangle_\xi & \langle F_{44}(\Theta) \rangle_\xi \end{bmatrix}. \quad [26]$$

Furthermore,

$$\langle F_{12}(0) \rangle_\xi = \langle F_{12}(\pi) \rangle_\xi = 0, \quad \langle F_{34}(0) \rangle_\xi = \langle F_{34}(\pi) \rangle_\xi = 0. \quad [27]$$

For spherically symmetric particles, the number of independent scattering matrix elements reduces to four owing to

the identities $\langle F_{22}(\Theta) \rangle_\xi \equiv \langle F_{11}(\Theta) \rangle_\xi$ and $\langle F_{44}(\Theta) \rangle_\xi \equiv \langle F_{33}(\Theta) \rangle_\xi$. As a consequence, measurements of the linear backscattering depolarization ratio

$$\delta_L = \frac{\langle F_{11}(\pi) \rangle_\xi - \langle F_{22}(\pi) \rangle_\xi}{\langle F_{11}(\pi) \rangle_\xi + \langle F_{22}(\pi) \rangle_\xi}, \quad 0 \leq \delta_L \leq 1 \quad [28]$$

and the closely related circular backscattering depolarization ratio

$$\delta_C = \frac{\langle F_{11}(\pi) \rangle_\xi + \langle F_{44}(\pi) \rangle_\xi}{\langle F_{11}(\pi) \rangle_\xi - \langle F_{44}(\pi) \rangle_\xi} = \frac{2\delta_L}{1 - \delta_L} \geq \delta_L \quad [29]$$

are among the most reliable means of detecting particle nonsphericity.

Measurement and Computation of Single-Particle Characteristics

Evaluation of the Earth's radiation balance and analyses of remote-sensing observations require accurate quantitative knowledge of average single-particle optical characteristics as functions of particle size, morphology, and composition. This knowledge can be based on theoretical computations or experimental measurements, both approaches having their strengths and limitations. Theoretical modeling does not involve expensive instrumentation and allows switching to another particle shape, size, or refractive index by changing a few lines in a computer code. However, numerically exact computations for realistic polydispersions of morphologically complex particles are costly, if even possible, and are often replaced by computations for idealized shapes, whereas approximate calculations often have uncertain accuracy and range of applicability. Experimental measurements deal with real particles, but require complex and expensive hardware and may be difficult to interpret.

Measurements

Detectors of visible and infrared light are usually polarization insensitive, so their response is determined by only the first Stokes parameter of the incoming beam. In order to measure all elements of the scattering matrix, one must insert into the beam various optical elements that can vary the polarization state of light before and after scattering in a controllable way (Figure 5). The use of high-frequency sinusoidal modulation in the time of the polarization of light before scattering combined with intensity normalization and followed by lock-in detection increases the measurement accuracy and yields several elements from only one detected signal. The measurement procedure is repeated at different scattering angles in order to determine the angular profile of the scattering matrix.

Scattering measurements using visible and infrared light benefit from the availability of sensitive detectors (photo-multipliers and avalanche semiconductor photodiodes), intense sources of radiation (lasers), and high-quality optical elements. They involve relatively inexpensive and portable instrumentation and can be performed in the field nearly as well as in the laboratory. However, they often suffer from poor advance knowledge of microphysical characteristics of scattering particles, thereby making difficult comparisons of experimental and theoretical results. The arrangement of the source of light and the detector precludes measurements at scattering angles close to 0° and 180° , which makes problematic the absolute measurement of the (1,1) element of the scattering matrix and the scattering cross-section.

The main idea of the microwave analog technique is to manufacture a centimeter-sized scattering object with desired shape and refractive index, measure the scattering of a microwave beam by this object, and finally extrapolate the results to other wavelengths (e.g., visible or infrared) by keeping the ratio of size and wavelength fixed. This allows one to determine so-called scale-invariant characteristics such as the phase

Figure 5 Schematic view of an experimental scattering setup using visible or infrared light. The laser beam passes several optical elements before and after scattering and is detected by the photomultiplier. The latter is mounted on a circular rail and can be moved around the particle jet in order to cover a wide range of scattering angles. function $p(\Theta) = 4\pi \langle F_{11}(\Theta) \rangle_{\xi} / \langle C_{\text{sca}} \rangle_{\xi}$ or ratios of the elements of the scattering matrix. Microwave measurements allow a wide coverage of scattering angles, including the exact forward and backward directions, and a much greater degree of control over the target size, shape, and orientation than do optical measurements. However, the microwave measurements require more cumbersome and expensive instrumentation and large measurement facilities. Furthermore, they are performed for only one particle size, shape, and orientation at a time, thereby making ensemble averaging a time-consuming process.

Theoretical Techniques

All of the needs of a practitioner dealing with electromagnetic scattering by spherical particles may be well served by the exact and highly efficient Lorenz–Mie theory, which is the result of applying the separation-of-variables method to the Maxwell equations in spherical coordinates. There are extensions of the Lorenz–Mie theory applicable to concentric layered spheres.

For nonspherical particles, numerically exact computations must resort to more general and complex solutions traditionally divided into two broad categories. Differential equation methods compute the scattered field by solving the Maxwell equations, subject to appropriate boundary conditions, in the frequency domain or in the time domain. Integral equation methods are based on the volume or surface integral counterparts of the Maxwell equations; the boundary conditions are included in the solution automatically. Perhaps the most popular and widely used techniques are the *T*-matrix method, the discrete dipole approximation, and the finite-difference time-domain method. These techniques have somewhat different ranges of applicability in terms of particle morphology, refractive index, and size relative to the wavelength.

The practical importance of approximate treatments of light scattering diminishes as various exact techniques mature and become applicable to a wider range of problems, and as computers become ever more powerful. However, at least one phenomenological approach is unlikely to become obsolete in the near future because its accuracy can only be expected to improve as the ratio of the particle size to the wavelength grows, while numerically exact theoretical techniques for nonspherical particles cease to be practical whenever this ratio exceeds a certain threshold. This so-called geometrical optics approximation assumes that the particle size is much larger than the wavelength and that the incident plane wave can be represented as a collection of ‘independent parallel rays.’ The history of each ray impinging on the particle surface is traced using Snell’s law and Fresnel formulas (Figure 6). Sampling all escaping rays into predefined narrow angular bins yields a quantitative representation of the particle scattering and absorption properties. The ray-tracing pattern is supplemented by computation of the Fraunhofer diffraction of the incident wave on the particle projection.

Solution of the RTE

Based on the specific problem at hand, the RTE [24] must be supplemented by appropriate boundary conditions. For example, a standard model of the atmosphere is a multilayer

Figure 6 Ray-tracing diagram.

plane-parallel system illuminated from above by solar radiation and bounded from below by a horizontally homogeneous reflecting surface. Then the RTE can be solved numerically using efficient techniques such as the adding and doubling, discrete ordinate, and invariant imbedding methods. Complex horizontally and vertically inhomogeneous models can be handled using the less efficient but more flexible Monte Carlo technique.

Despite the expressly vectorial nature of electromagnetic scattering, the RTE [24] is often replaced by a simplified scalar version in which one keeps only the first Stokes parameter (i.e., the intensity) and only the (1,1) elements of the extinction and phase matrices. Although it is much easier to solve the scalar RTE, it is important to remember that it has no physical justification and can result in significant errors in the computed intensity.

Figure 7 Scattering efficiency factor versus size parameter for poly-disperse spherical particles with refractive indices 1.33 and 1.45.

Figure 8 Phase functions for water cloud droplets, hexagonal ice columns, and randomly shaped ice crystals.

Figure 9 Global albedo of a liquid water cloud relative to that of an optical-thickness-equivalent ice cloud composed of irregular particles (dotted curve) and hexagonal columns (solid curve).

Examples of Scattering by Clouds and Aerosols

The few following examples serve to illustrate some key features of electromagnetic scattering phenomena and their use in remote sensing of aerosols and clouds and in radiation budget computations. **Figure 7** shows the scattering efficiency factor Q_{sca} versus size parameter x for a narrow size distribution of spherical particles with refractive indices $m = 1.33$ and 1.45 (typical of water and sulfate aerosols at visible wavelengths,

Figure 10 Linear polarization versus scattering angle for polydisperse spherical particles with varying size parameters x and refractive indices m .

respectively). The size parameter is defined as $x = 2\pi r_{\text{eff}}/\lambda$, where r_{eff} is the effective radius of the size distribution. The scattering efficiency is defined as the ratio of the average scattering cross-section to the average area of the particle geometrical projection. One can see that for wavelength-sized particles ($x \sim 5$), $\langle C_{\text{sca}} \rangle_{\xi}$ can exceed the particle geometrical cross-section by a factor greater than 3.5. As the particle size becomes much larger, Q_{sca} tends to the asymptotic geometrical-optics value of 2, with equal contributions from the rays striking the particle and the light diffracted by the particle projection. For particles much smaller than the wavelength, $Q_{\text{sca}} \propto \lambda^{-4}$, as first demonstrated by Lord Rayleigh and hence called Rayleigh scattering. The presence of a well-defined maximum in the scattering efficiency curve for a relatively narrow polydispersion (**Figure 7**) creates the possibility of an infrequent phenomenon for which aerosol particles of just the right size have a lower extinction efficiency factor in the blue than that at the larger wavelengths in the red. Thus, in contrast to the familiar

Figure 11 Linear depolarization ratio versus surface-equivalent sphere size parameter for polydisperse, randomly oriented ice spheroids and cylinders. The refractive index is 1.311. ϵ is the ratio of the largest to the smallest axes of a spheroid. The shapes of prolate and oblate cylinders are specified by length-to-diameter L/D and diameter-to-length D/L ratios, respectively.

reddening of the setting sun owing to enhanced Rayleigh scattering, a sufficiently narrow size distribution of aerosol particles in the atmosphere can produce a blue cast to the sun or moon and is perhaps responsible for the implied rarity associated with the phrase ‘once in a blue moon.’

The dotted curve in Figure 8 shows the phase function typical of spherical cloud droplets at visible wavelengths. The strong concentration of light at $\Theta = 0^\circ$ is produced by Fraunhofer diffraction of light on the particle projection, whereas the feature at $\Theta \sim 140^\circ$ is the primary rainbow generated by rays that have undergone only one internal reflection (Figure 6). The slight change of the rainbow angle with wavelength caused by dispersion gives rise to spectacularly

colorful rainbows often observed during showers illuminated by the sun at an altitude lower than about 40° . The enhanced intensity at $\Theta \sim 180^\circ$ is called the glory and can be seen from an airplane as a series of colored rings around the shadow cast by the airplane on the cloud top.

The dashed curve in Figure 8 depicts the phase function typical of randomly oriented pristine hexagonal ice crystals. The concentrations of light at $\Theta \sim 22^\circ$ and 46° are the primary and secondary halos attributed to minimum angles of deviation by 60° and 90° ice prisms. These features represent only two of many optical phenomena associated with regularly shaped ice crystals. Since cirrus clouds rather often fail to exhibit halos, the majority of real ice crystals appear to have

highly irregular shapes and rough rather than flat surfaces. Such particles are better characterized by featureless phase functions like the one shown in Figure 8 by the solid curve and computed for a random-fractal model of ice crystals.

Large numerical differences between the three phase functions depicted in Figure 8 can cause significant differences in bidirectional reflectance of optical-thickness-equivalent water and ice clouds (optical thickness is defined as the average extinction cross-section per particle times the column particle number concentration). This, in turn, may lead to significant errors in the retrieved cloud optical thickness if remote-sensing reflectance measurements are inverted using an incorrect particle model.

Figure 9 illustrates the effect of particle shape on the global cloud albedo (defined as cloud reflectance averaged over all incidence and reflection directions) at visible wavelengths. The quantity $(1 - \text{cloud albedo})$ determines how much solar energy is absorbed or transmitted by the atmosphere and is an important climatological parameter. It is seen that for the same optical thickness, clouds composed of irregular ice crystals have the largest albedo, whereas those composed of water droplets are the least reflective. This result can be explained by very large differences between the respective phase functions at side-scattering angles, which are well seen in Figure 8.

Figure 10 illustrates the ratio $P(\Theta) = -\langle F_{12}(\Theta) \rangle_{\xi} / \langle F_{11}(\Theta) \rangle_{\xi}$ of the scattering matrix elements (called the degree of linear polarization of the scattered light for unpolarized incident light) for polydisperse spheres with different refractive indices and size parameters. The obvious significant variability of polarization with m and r_{eff} (or λ) makes it a very sensitive indicator of the particle microphysical properties. Furthermore, since P is a ratio of two intensities, it can be measured to a much greater precision than intensity. These two factors explain the remarkable potential of photopolarimetry as a remote-sensing tool for aerosol and cloud particle characterization.

Finally, Figure 11 demonstrates the linear depolarization ratio [28] for polydisperse, randomly oriented, nonspherical ice particles. It is well seen that the growth of the size parameter from 0 to about 10 rapidly changes δ_L from zero to large values sometimes approaching the theoretical limit $\delta_{L,\text{max}} = 1$. This

behavior of backscattering depolarization makes it useful for sizing aerosol, cloud, and precipitation particles by performing multiwavelength lidar and radar measurements. It is also obvious that although backscattering depolarization is a reliable indicator of the presence of nonspherical particles, its magnitude is not always a good measure of the degree of particle nonsphericity.

Ultraviolet Radiation

K Stammes, Stevens Institute of Technology, Hoboken, NJ, USA

Synopsis

This article provides a review of ultraviolet radiation in the atmosphere–ocean system with emphasis on the basic interaction with molecules and suspended particles in both media as well as the reflection and refraction occurring at the air–water interface. A comparison between measured and computed irradiances in the ocean is provided to illustrate the utility of the modeling. The model is also used to discuss the impact of an ozone depletion at high latitudes the primary production in the water column.

Introduction

Life on Earth began with light. Before oxygen developed in the Earth's atmosphere the ocean as well as fresh water bodies served as a suitable environment for the evolution of Earth's early life forms, because water provided protection from the damaging ultraviolet radiation (UVR) from the Sun. Photoinduced chemical reactions led to photosynthesis. Oxygen produced by photosynthetic bacteria led to the formation of ozone, and eventually to life forms that could develop also on land, because the ozone layer provided vital protection against harmful UVR.

In the primordial atmosphere, and today as well, the formation of *photochemically active* species is initiated by ultraviolet and visible solar radiation through the process of *photolysis*, in which molecules are split up into atoms and smaller molecules. Photolysis of the oxygen molecule (O_2) leads to the formation of oxygen atoms (O). Ozone is then formed when an oxygen atom and an oxygen molecule combine to yield O_3 . Chemical reactions catalyzed by photolysis are responsible for the destruction of atmospheric ozone. The bulk of the ozone resides in the stratosphere (15–50 km), where its abundance is determined by a balance between production and loss processes. The ozone production depends on the photolysis of O_2 , which is proportional to the product of the solar flux of dissociating UVR and the density of the O_2 gas (see eqn [7]). The solar UV light intensity falls off rapidly with depth into the atmosphere, due to absorption and scattering by atmospheric gases, whereas the number density of O_2 molecules decreases exponentially with height. Thus, the production of ozone will have a maximum at that height where the two curves cross each other.

This article provides a description of how UVR interacts with molecules and suspended matter in the atmosphere and in the ocean. It gives a basic description of this interaction, as well as examples of how UV penetration into the ocean is affected by the stratospheric ozone layer, and by suspended particles in the ocean.

Spectrum of Electromagnetic Radiation from the Sun

An overview of the various parts of the solar spectrum is provided in Table 1. The spectral variable is the wavelength $\lambda = c/\nu$, where c is the speed of light and ν is the frequency (s^{-1}) or (Hz). In the UV

and visible spectral range, λ is expressed in nanometers ($1 \text{ nm} = 10^{-9} \text{ m}$). The irradiance in each spectral range is listed as well as the known percentage solar variability, defined as the maximum minus minimum divided by the minimum.

Figure 1 shows the UV, visible, and near-infrared part of the spectral solar irradiance (wavelengths shorter than 1000 nm) measured on board an earth-orbiting satellite, above the atmosphere. Spectra of ideal blackbodies at several temperatures are also shown in Figure 1. Requiring that the total energy emitted be the same as a blackbody, one finds that the Sun's effective temperature is 5778 K. If the radiating layers of the Sun had a uniform temperature at all depths, its spectrum would match one of the theoretical blackbody curves exactly. Therefore, the deviations are the result of emission from a nonisothermal solar atmosphere. Some of the more important aspects of the UV/visible spectrum are: (1) most of the emission arises within the *photosphere* where the Sun's visible optical depth reaches unity, while the finer structure is due to *Fraunhofer absorption* by gases in the cooler (higher) portions of the photosphere; (2) for $125 < \lambda < 380 \text{ nm}$, the effective radiating temperature falls to values as low as 4500 K, due to increased numbers of overlapping absorbing lines. At still shorter wavelengths, some of the emission originates in the hotter *chromosphere*, which overlies the photosphere, and the effective temperature increases; and (3) the UV irradiance depends noticeably upon the solar cycle, being more intense at high than at low solar activity.

Sun–Earth Geometry

Since the Earth moves around the Sun in an elliptical orbit, the Earth–Sun distance, R_n , varies throughout the year, such that on day number d_n (0 for 1 January, 364 for 31 December)

$$R_n = R_0(a_0 + a_1 \cos \theta_n + a_2 \sin \theta_n + a_3 \cos 2\theta_n + a_4 \sin 2\theta_n)^{-1/2} \quad [1]$$

where R_0 is the average Earth–Sun distance. The coefficients are $a_0 = 1.000110$, $a_1 = 0.034221$, $a_2 = 0.001280$, $a_3 = 0.000719$, $a_4 = 0.000077$, and $\theta_n \equiv 2\pi d_n/365$ (radians). R_n varies by about 3.4% from its minimum value on about 3 January to its maximum value on about 3 July. Thus, the variation in R_n^2 and therefore in the extraterrestrial solar irradiance, is about 6.9%. This variation implies that the UV exposure is almost 7% larger

Table 1 Subregions of the spectrum

Subregion	Irradiance (W m^{-2})	Solar variability	Comments
Far UV ($100 < \lambda < 200 \text{ nm}$)	<1	7–80%	Dissociates O_2 . Discrete electronic excitation of atomic resonance lines.
Middle UV, or UV-C ($200 < \lambda < 280 \text{ nm}$)	6.4	1–2%	Dissociates O_3 in intense Hartley bands. Potentially lethal to biosphere.
UV-B ($280 < \lambda < 320 \text{ nm}$)	21.1	$<1\%$	Some radiation reaches surface, depending on O_3 optical depth. Damaging to biosphere. Responsible for skin erythema.
UV-A ($320 < \lambda < 400 \text{ nm}$)	85.7	$<1\%$	Reaches surface. Benign to humans. Scattered by clouds, aerosols, and molecules.
Visible, or PAR ($400 < \lambda < 700 \text{ nm}$)	532	$\leq 0.1\%$	Absorbed by ocean, land. Scattered by clouds, aerosols, and molecules. Primary energy source for biosphere and climate system.
Near IR ($0.7 < \lambda < 3.5 \mu\text{m}$)	722	–	Absorbed by O_2 , H_2O , CO_2 in discrete vibrational bands.

Figure 1 Extraterrestrial solar irradiance, measured by a spectrometer on board an Earth-orbiting satellite. The UV spectrum ($119 < \lambda < 420 \text{ nm}$) was measured by the SOLSTICE instrument on the UARS satellite (modified from a diagram provided by G.J. Rottmann, private communication, 1995). The vertical lines divide the various spectral subranges defined in Table 1. The smooth curves are calculated blackbody spectra for a number of emission temperatures.

in the Southern Hemisphere in January, than at the same latitude in the Northern Hemisphere in July. The illumination of the Earth's surface depends on the *solar zenith angle*, θ_0 , which is the angle between the local vertical and the direction of the center of the solar disk. The complementary angle between the local horizon and the Sun is called the *solar elevation angle*. The solar zenith angle depends on the time of the day, the time of the year, and geographic location. Thus, the solar illumination varies on diurnal, seasonal, as well as the 11-year solar cycle timescales.

Interaction of UV Light with Absorbing and Scattering Media

To describe the interaction of light with the atmosphere and the ocean (or freshwater bodies), it is convenient to think of such

media as composed of radiatively active 'particles' that absorb and scatter light. In the atmosphere, these particles consist of molecules, aerosols, and cloud droplets or ice crystals. In the ocean, they consist of molecules (although strictly speaking the scattering by pure water is caused by molecular density fluctuations) and hydrosols (suspended particles of organic and inorganic origin).

Definitions of Irradiance and Radiance

The spectral net irradiance F_ν within a small frequency range ν to $\nu + d\nu$ is the net energy d^3E crossing a surface element dA per unit time and per unit frequency: $F_\nu = \frac{d^3E}{dA dt d\nu} = F_\nu^+ - F_\nu^- [\text{W} \cdot \text{m}^{-2} \cdot \text{Hz}^{-1}]$. Here, we have introduced the spectral

hemispherical irradiances $F_\nu^+ = d^3E^+/dA dt d\nu$ and $F_\nu^- = d^3E^-/dA dt d\nu$.

The *directional dependence* of the energy flow is obtained by considering the energy d^4E that flows within a solid angle $d\omega$ around direction $\hat{\Omega}$ in the time interval dt and within the frequency range $d\nu$. The *spectral radiance* I_ν is defined as the energy per unit area per unit solid angle, per unit frequency, and per unit time that passes through a surface element dA : $I_\nu = d^4E/\cos\theta dA dt d\omega d\nu$ ($\text{W}\cdot\text{m}^{-2}\cdot\text{sr}^{-1}\cdot\text{Hz}^{-1}$), where θ is the angle between the surface normal $\hat{n}$ and the direction of propagation $\hat{\Omega}$. From these definitions, the spectral net irradiance can be expressed as: $F_\nu = F_\nu^+ - F_\nu^- = \int_+ d\omega \cos\theta I_\nu - \int_- d\omega \cos\theta I_\nu = \int_{4\pi} d\omega \cos\theta I_\nu$, where the subscripts $+$ and $-$ on the integral signs denote integration over each hemisphere. Finally, we define the mean intensity as: $\bar{I}_\nu = (1/4\pi) \int_{4\pi} d\omega I_\nu$, which is simply the radiance averaged over the sphere. Integration over all frequencies yields the *net irradiance* $F = \int_0^\infty d\nu F_\nu$ and the *actinic radiation* $4\pi\bar{I} = 4\pi \int_0^\infty d\nu \bar{I}_\nu$ both in units of ($\text{W}\cdot\text{m}^{-2}$).

Absorption, Scattering, and Extinction by Molecules and Particles

It is found experimentally that if a beam of light is incident on a thin layer of thickness ds consisting of radiatively active constituents, then the light is attenuated so that the differential loss in radiance is $dI_\nu = -k(\nu)I_\nu ds$, where k is called the extinction coefficient. Integration yields

$$I_\nu(s, \hat{\Omega}) = I_\nu(0, \hat{\Omega}) \exp[-\tau_s(\nu)]. \quad [2]$$

Here, $\hat{\Omega}$ denotes the propagation direction of the beam, and the dimensionless extinction optical path or opacity along the path s is given by $\tau_s(\nu) \equiv \int_0^s ds' k(\nu)$. The extinction optical path of a mixture of scattering/absorbing molecules and particles is defined as the sum of the individual scattering optical path, $\tau_{sc}(\nu)$, and the absorption optical path, $\tau_a(\nu) = \tau_{sc}(\nu) + \tau_a(\nu)$, where $\tau_{sc}(\nu) = \int_0^s ds' \sum_i \sigma^i(\nu, s') = \int_0^s ds' \sigma(\nu, s')$ and $\tau_a(\nu) = \int_0^s ds' \sum_i \alpha^i(\nu, s') = \int_0^s ds' \alpha(\nu, s')$. The sum is over all optically active species, and $\sigma^i(\nu, s')$ and $\alpha^i(\nu, s')$ (m^{-1}) are the individual scattering and absorption coefficients. The total extinction coefficient is $k(\nu, s') = \alpha(\nu, s') + \sigma(\nu, s')$.

Absorption by molecules in the Earth's atmosphere is due to radiatively active trace gases. For UVR and visible light the most important gas is ozone, but oxides of sulfur and nitrogen may (depending on location) have a significant effect on the UVR penetration. The molecular absorption coefficient is: $\alpha_m(\lambda) = \alpha_{n, \text{O}_3} n_{\text{O}_3}$, where the subscript m stands for molecules, and α_{n, O_3} and n_{O_3} are the ozone absorption cross section and number density, respectively (Figure 2(a) and 2(b)). At wavelengths longer than 310 nm the ozone absorption is due to the *Huggins bands*, whereas the spectrally broad but weak absorption between 450 and 700 nm is due to the *Chappuis bands* (Figure 2(a)). Scattering by molecules in the atmosphere is proportional to the gas density. Thus, the scattering coefficient due to scattering by air molecules is: $\sigma_m(\lambda) = \sigma_{n, \text{Ray}}(\lambda) n_m$, where $\sigma_{n, \text{Ray}}(\lambda) \sim \lambda^{-4}$ is the Rayleigh scattering cross section, and n_m is the total air number density (Figure 2(b)).

Absorption by pure water results from mutual interactions between the intermolecular forces. Calculation of absorption cross sections from first principles is very difficult. Thus, laboratory and *in situ* measurements become essential for establishing the absorption coefficient $\alpha_{n, w}(\lambda)$ for pure water (Figure 2(c)). Scattering in pure water is due to clusters of molecules and ions, much smaller than the wavelength of light, and from an optical point of view the clusters are uncorrelated. Thus, the wavelength dependence of the scattering cross section for pure water is similar to the Rayleigh scattering cross section for molecules in the atmosphere, and the scattering coefficient for pure water can be approximated by $\sigma_w(\lambda) = \left(\frac{129}{\lambda}\right)^{4.32}$, λ in (nm).

Gaseous Absorption and Penetration Depth

Figure 3 shows that significant O_2 absorption occurs in the *Schumann-Runge bands* between 195 and 175 nm. At shorter wavelengths this feature merges into the very intense *Schumann-Runge continuum* (130–175 nm).

An instructive way of looking at the effects of gaseous absorption on incoming radiation is through the concept of *penetration depth*, defined as the height at which the solar radiation reaches optical depth unity, for a clear atmosphere exposed to an overhead Sun. The UV penetration depth for wavelengths shorter than 320 nm is shown in Figure 4. The smallest penetration depths, occurring in the thermosphere, arise from the very high absorption coefficients of air in the X-ray ($\lambda < 10$ nm) and extreme-UV ($10 < \lambda < 100$ nm) spectral range. The far-UV solar radiation between 100 and 200 nm (see Table 1) is absorbed in the lower thermosphere and mesosphere (50–120 km). Middle-UV, or UV-C ($200 < \lambda < 280$ nm) atmospheric absorption is dominated by the intense *Hartley bands* due to O_3 . In the absence of O_3 , the Earth's land and ocean surface would be irradiated directly by UV-C to the detriment, if not the total eradication of surface life. The absorption of this important energy band causes the inversion in the Earth's stratospheric (15–50 km) temperature profile.

Light at UV wavelengths penetrating to the troposphere and surface, is customarily divided into two groups: UV-B (280–320 nm) and UV-A (320–400 nm). Living organisms are much more sensitive to damage by UV-B radiation than by radiation in the more benign UV-A region. Penetration of UV-B radiation is very sensitive to the total column abundance of O_3 . At longer wavelengths, the photosynthetically active radiation (PAR) spans the spectral range between 400 and 700 nm. This spectral range has the greatest clear-air transparency (except for radio waves), because it contains only the weak absorption features of O_2 and O_3 . The eyes of humans (and animals) are most sensitive to light in this spectral range, a fact of extreme importance for evolutionary adaptation.

UV Light Transport in the Atmosphere–Ocean System

If we are interested primarily in energy transport, it is sufficient to consider the azimuthally averaged radiance $I_\nu(z, u)$, where z

Figure 2 (a) Absorption cross section of ozone. (b) Number density of atmospheric ozone (dashed line) and total air number density (solid line). (c) Absorption spectrum for pure ice (dashed line), and for pure water (solid line). (d) Chlorophyll-specific absorption spectrum normalized at 440 nm.

Vertical arrows indicate the ionization thresholds of the various species. Adapted with permission from Thomas, G.E., Stamnes, K., 1999. Radiative Transfer in the Atmosphere and Ocean. Cambridge University Press, Cambridge.

denotes the level in the medium (height in the atmosphere or depth on the ocean), and $u = \cos \theta$, θ being the polar angle. It is convenient to split the radiation field into two parts: (1) the *direct* solar beam, which is exponentially attenuated upon passage through the atmosphere and ocean, and (2) the *diffuse* or scattered radiation.

According to eqn [2] the penetration of the direct solar beam through the atmosphere may be written as (dropping the subscript ν) $I_{\text{sol}}(z) = I_{\text{sol}}(\tau(z)) = F^s e^{-\tau}$. Here, F^s is the solar irradiance (normal to the solar beam direction) incident at the top of the atmosphere. Unless the Sun is close to the horizon, it is sufficient to use *plane geometry*, assuming that the atmosphere

and the ocean are stratified media, for which the optical properties vary only in the vertical. Then the *vertical* optical depth τ_ν is defined as $\tau_\nu(z) \equiv \tau_s \mu_0 \equiv \sum_i \int_z^\infty dz' k(\nu, z')$, or $d\tau_\nu(z) = -k(\nu, z) dz$, where $\mu_0 = \cos \theta_0$, and θ_0 is the solar zenith angle as illustrated in Figure 5. In plane geometry, the diffuse radiation in the medium is described by:

$$u \frac{dI_\nu(z, u)}{dz} = -k(\nu, z) I_\nu(z, u) + \frac{\sigma(\nu, z)}{2} \int_{-1}^1 du' p(z, u', u) I_\nu(z, u') + S_\nu^*(z, u). \quad [3]$$

Figure 5 Schematic illustration of two adjacent media with a flat interface such as the atmosphere overlying a calm ocean. The atmosphere has a different index of refraction ($m_r \approx 1$) than the ocean ($m_r \approx 1.33$). Adapted with permission from Thomas, G.E., Stamnes, K., 1999. Radiative Transfer in the Atmosphere and Ocean. Cambridge University Press, Cambridge.

Equation [3] has a simple physical interpretation. The term on the left side is the change in the radiance along the slant path dz/u . The first term on the right side is the loss of radiation out of the beam due to extinction. The second term is the gain due to multiple scattering, and the normalized angular scattering cross section, $p(z, u', u)$, gives the probability that light is scattered from direction u' into direction u . The third term is the solar pseudo-source, proportional to the attenuated solar beam, which 'drives' the diffuse radiation. Instead of the geometrical distance dz it is customary to use the nondimensional optical depth, $d\tau(z) = -k(z)dz$ as the independent variable. Then, we may rewrite eqn [3] as follows (dropping the subscript ν):

$$u \frac{dI(\tau, u)}{d\tau} = I(\tau, u) - \frac{a(\tau)}{2} \int_{-1}^1 du' p(\tau, u', u) I(\tau, u') - S^*(\tau, u) \quad [4]$$

where the single-scattering albedo is defined as $a(\tau(z)) \equiv \sigma(z)/k(z)$. The source term $S^*(\tau, u)$ is defined below.

Surface Reflection and Transmission

Knowledge of the reflectance of underlying land and ocean surfaces is necessary for calculating the diffuse radiation field. Also, in shallow waters, the reflectance of the ocean bottom influences the diffuse radiation in the water and the radiation leaving the water surface. The reflectance and transmittance of a surface depend upon both the angles of incidence and reflection or transmission. In atmospheric radiative transfer, it is frequently assumed that the underlying land or ocean surface reflects incoming radiation isotropically. Such a surface is called a *Lambert* reflector, and the reflectance is called the surface albedo, ρ_L . However, most natural surfaces are non-Lambertian. Thus, we could relax the assumption of a Lambert reflector and use instead the bidirectional reflection distribution function, if this function is known. For the coupled atmosphere-ocean system it is preferable to consider two strata, one for the atmosphere, and one for the ocean, but with different indices of refraction. The basic radiance, defined as I/m^2 where m is the real part of the index of refraction, is the relevant quantity when we consider two strata with different values of m . If we assume for simplicity that the interface is flat and smooth (a calm ocean), then the basic radiance must satisfy Snell's law and Fresnel's equations. As illustrated in Figure 5, the downward radiation distributed over 2π sr in the atmosphere will be restricted to a cone less than 2π sr (referred to as region II in Figure 5) after being refracted across the interface into the ocean. Beams outside the refractive region in the ocean are in the total reflection region (referred to as region I in Figure 5). The demarcation between the refractive and the total reflection region in the ocean is given by the critical angle $\mu_c = \sqrt{1 - 1/m_r^2}$, where $m_r = m_{\text{ocean}}/m_{\text{air}}$ is the index of refraction of the ocean relative to the air.

Since the radiation field in the ocean is driven by solar radiation passing through the air-water interface, eqn [4]

applies also in the ocean, but the solar pseudo-sources are different. In the atmosphere, we have

$$S_{\text{air}}^*(\tau, u) = \frac{a(\tau)}{4\pi} p(\tau, -\mu_0, u) e^{-\tau/\mu_0} + \frac{a(\tau)}{4\pi} \rho_s(-\mu_0; m_r) p(\tau, \mu_0, u) e^{-(2\tau_s - \tau)/\mu_0} \quad [5]$$

where the first term is the usual solar beam pseudo-source, and the second term is due to the reflection occurring at the interface, which is proportional to $\rho_s(-\mu_0; m_r)$, the specular reflection coefficient. The pseudo-source in the ocean is just the attenuated solar beam refracted through the interface:

$$S_{\text{ocean}}^*(\tau, u) = \frac{a(\tau)}{4\pi} \frac{\mu_0}{\mu_t} \tau_s(-\mu_0; m_r) p(\tau, -\mu_t, u) e^{-\tau/\mu_0} e^{-(\tau - \tau_s)/\mu_t} \quad [6]$$

where $\tau_s(-\mu_0; m_r)$ is the beam transmittance through the interface, and μ_t is the cosine of the solar zenith angle in the ocean, which is related to μ_0 by Snell's law $\mu_t \equiv \mu_t(\mu_0, m_r) = \sqrt{1 - (1 - \mu_0^2)/m_r^2}$. With the use of the appropriate pseudo-sources for the atmosphere [$S_{\text{air}}^*(\tau, u)$] and ocean [$S_{\text{ocean}}^*(\tau, u)$] eqn [4] can now be solved subject to boundary conditions at the top of the atmosphere and the bottom of the ocean. However, in addition we must properly account for the reflection and transmission through the interface by requiring that I/m^2 satisfies Snell's law and Fresnel's equations.

Photolysis Rate and Biological Dose Rate

In atmospheric photochemistry, the *photolysis rate* is defined as the local rate of a photoabsorption process leading to a specific photodissociation event. We express the photolysis rate coefficient for the photodissociation of a particular species i as follows:

$$J_i \equiv \int_{\nu_c}^{\infty} d\nu 4\pi (\bar{I}_\nu / h\nu) \alpha^i(\nu) \eta^i(\nu) \quad [s^{-1}]. \quad [7]$$

Here, $\alpha^i(\nu)$ is the photoabsorption cross section, $\eta^i(\nu)$ ($0 \leq \eta^i \leq 1$) is the *quantum yield* or efficiency by which the absorbed radiative energy produces the photodissociation, ν_c is the minimum frequency corresponding to the threshold energy for the photoabsorption, $\bar{I}$ is the mean intensity, and $4\pi \bar{I}_\nu / h\nu$ is the density of photons at a given frequency. Photochemists frequently use the term *actinic flux* for the quantity $4\pi \bar{I}_\nu$.

The rate at which a surface receives radiative energy capable of initiating certain biological processes is obtained by weighting the received radiation by a specific spectral function $A(\nu) < 1$ called the *action spectrum*, which gives the efficiency of a particular process, for example, the UV 'kill rate.' The rate at which a flat surface is 'exposed' is called the *dose rate*

$$D \equiv \int_0^{\infty} d\nu A(\nu) F_\nu^- \quad [W \cdot m^{-2}] \quad [8]$$

where F_ν^- is the incident irradiance. The *radiation dose* is defined to be the total time-integrated amount of energy received (usually over 1 day) $\int dt D(t)$.

Modeling UV Penetration into the Ocean

UV penetration in the ocean is strongly influenced by small plankton and thus by biological productivity, which provides a close link between biological and optical oceanography. Important aspects of the ozone depletion issue include the effects of increased UV levels on algae, plankton, and fish larvae. As sources of atmospheric sulfur compounds involved in cloud formation, plankton may indirectly affect atmospheric transmission, thereby linking atmospheric radiative transfer with ocean biology.

The impact of decreased ozone levels on aquatic ecosystems may be assessed by a radiation model that provides a solution of the radiative transfer equation for the coupled atmosphere–ocean system. The atmosphere is assumed to be separated from the ocean by a plane interface as explained above. The relative refractive index for air is taken to be unity and that of the ocean to be 1.33. To account for the vertical inhomogeneity of the atmosphere and water, the two media are divided into a sufficient number of layers to resolve the changes in optical properties with height in the atmosphere and depth in the ocean. To estimate the UV penetration through this coupled atmosphere–ocean system, we need the spectral distribution of the radiation incident at the top of the atmosphere (see Figure 1) as well as the optical properties of the atmosphere and water media. For a clear atmosphere, the optical properties are determined mainly by ozone absorption (see Figure 3), and molecular (Rayleigh) scattering.

Phytoplankton dwell in the top layers of the water column, the euphotic zone, because of their requirement for PAR radiation to drive photosynthesis. In the euphotic zone, they would be exposed to any increase in UVR. If all other factors remain constant, ozone depletion would lead to increased transmission of UV-B radiation through the atmosphere and into the water column. Model results indicate that UV-B radiation is significantly absorbed in the first couple of meters into the water. At high latitudes (70°), an ozone depletion of 30% (compared to normal) will increase UV-B exposure 10 m below the surface by as much as 33% on 1 October in the Southern Ocean, and by 23% at summer solstice. Thus, the relative amount of UV-B increase in the water column due to ozone depletion is most pronounced in spring, which happens to be the time when polar ozone depletion is most severe. Chlorophyll pigment reduces the penetration of UV-B radiation into the water. The larger the chlorophyll concentration, the less the UV-B transmission; however, the UV-B to PAR ratio is relatively unaffected by the chlorophyll concentration. Thus, species that depend on a certain level of PAR for photosynthesis and therefore adjust their depth in the water to optimize PAR will be exposed to a similar level of UV-B regardless of chlorophyll content.

Measured and Computed UV Irradiance in the Ocean

Underwater spectral irradiance was measured *in situ* with a UV/visible spectrometer submersed into the ocean off Palmer Peninsula, Antarctica. Figure 6 compares the measured and

Figure 6 Comparison between model computations (solid lines) and measurements (dotted lines) of depth vs $F_{\text{UV-B}}/F_{\text{total}}$. Inside the ozone hole, the ozone abundance was 150 DU, the solar zenith angle was 56° , and the vertical distribution of chlorophyll concentration was 0.57 mg m^{-3} from the surface to 20 m depth, 0.47 mg m^{-3} below 20 m. Outside the ozone hole, the ozone abundance was 350 DU, the solar zenith angle was 57° , and the vertical distribution of chlorophyll concentration was 1.9 mg m^{-3} from the surface to 10 m depth, 1.6 mg m^{-3} from 10 to 20 m, and 1.5 mg m^{-3} below 20 m.

computed ratio of the irradiance integrated across the UV-B range ($F_{\text{UV-B}}$, 280–320 nm) to that integrated across the complete measured range (F_{total} , 280–700 nm). Ratios for both undepleted ozone levels (350 DU, labeled ‘outside hole’) and depleted levels (150 DU, labeled ‘inside hole’) are shown. How well can this model reproduce the underwater downwelling irradiance, when it is constrained to yield the correct surface irradiance by adjusting the cloud/aerosol optical depth (which was not measured)? We note that there is good agreement between computed and measured ratios below the surface, but some curvature in the computed ratio just below the surface is absent in the ratio inferred from the measurements. A possible reason for this discrepancy is the neglect of surface waves in the model, which assumes a plane atmosphere–ocean interface.

Solar zenith angle has an important influence on UVR reaching the earth’s surface. It was overcast during the measurements, but the solar zenith angle was almost the same for the measurements taken inside and outside the ozone hole. Since the optical properties of clouds and aerosols depend weakly on wavelength, the impact of clouds and aerosols on the ratio ($F_{\text{UV-B}}/F_{\text{total}}$) is expected to be small. This circumstance allows us to investigate the impact of changes in ozone abundance on the surface and submarine irradiance ratio. Ozone depletion will increase the surface and underwater UV irradiance. Although the vertical distributions of chlorophyll in the water were different under and outside the ozone hole, the impact of this difference on the vertical variation in the ratio $F_{\text{UV-B}}/F_{\text{total}}$ is small. Thus, the vertical attenuation coefficients are nearly the same inside and outside the ozone hole. Therefore, if UV-B exposure is doubled at the surface, it will be doubled at all depths, and the critical depth above which UV-B damage may occur will be correspondingly deeper in the water column.

Impact of Ozone Depletion on Primary Productivity

Many marine organisms are sensitive to UVR. The extent to which these marine organisms will be able to adapt to expected increases in UV exposure is uncertain due to a sparsity of measurements. Increased levels of UV-B radiation may impact phytoplankton communities by (1) initiating changes in cell size and taxonomic structure, (2) reducing the productivity, (3) influencing the protein content, dry weight, and pigment concentration, (4) inducing chloroplast damage, and (5) directly affecting the proteins of the photosynthetic apparatus.

To explore the potential impact of ozone depletions, one may use a simple model, in which marine photosynthesis (or primary production, ignoring respiratory losses) is parameterized as follows

$$P = P_s \left(1 - e^{I_p/I_s}\right) \frac{1}{1 + I^*} \quad [9]$$

where P_s is the maximum photosynthesis in the absence of UVR inhibition, and I_p is the photosynthetically utilizable radiation (PUR):

$$I_p = \int_{400}^{700} \bar{I}(\lambda) a^*(\lambda) d\lambda. \quad [10]$$

Here, $\bar{I}(\lambda)$ is the mean intensity (scalar irradiance) and $a^*(\lambda)$ is the normalized algal absorption spectrum. In eqn [9], I_s is the PUR saturation level, and $1/(1 + I^*)$ describes the inhibition caused by UVR, where I^* is

$$I^* = \int_{280}^{400} \varepsilon(\lambda) \bar{I}(\lambda) d\lambda, \quad [11]$$

and $\varepsilon(\lambda)$ is the action spectrum for UVR-induced inhibition of photosynthesis.

The solar irradiance $\bar{I}(\lambda)$ that drives and inhibits primary photosynthesis depends on several environmental factors including the total ozone column amount, solar elevation, and depth in the ocean, as well as the presence of clouds, ice, and snow. Employing the radiative transfer model described above for the coupled atmosphere–sea ice–ocean system, and assuming total ozone column amounts of 400 and 200 DU, one may compute $\bar{I}(\lambda)$ at the bottom of the snow-covered sea ice and at various depths of open water, and the resulting $\bar{I}(\lambda)$ values may be used in eqn [9] to calculate the primary productivity. The results of such a study shows that (1) an ozone depletion increases not only harmful UVR, but also beneficial PUR; (2) at high latitudes the benefits of increased PUR for phytoplankton under sea ice and below a certain depth in the ocean dominates over the damage caused by increased UVR; (3) a large fraction of the primary production in the polar regions is caused by ice algae growing in environments well protected from UVR; and (4) the primary production in the polar regions could increase by as much as 1% for a 50% ozone depletion.

Introduction

The extraterrestrial solar radiation is dominated by visible and near-infrared wavelengths, and only a small portion of the energy is within the UV region. Furthermore, only a fraction of this UV radiation incident at the top of the atmosphere is transmitted to the Earth's surface. This transmitted UV radiation is nevertheless of great importance, because the photon energies in this spectral region are sufficient to damage bonds in molecules such as DNA, the 'building block of life'. This has led to concerns that increases in UV radiation resulting from ozone depletion will have further detrimental environmental effects. These include health effects in humans (e.g., damage to skin and eyes), damage to aquatic and terrestrial plants and ecosystems, and damage to materials. Small changes in ozone can lead to relatively large changes in UV radiation reaching the Earth's surface: it has been estimated that for each 1% reduction in ozone, the incidence rate for skin cancer will increase by 2–3% if all other factors remain unchanged.

Here the factors controlling UV irradiance at the Earth's surface are discussed. The concept of weighted UV irradiances is introduced along with methods to assess the sensitivity to ozone change. These are applied particularly to the recently defined UV Index – a standardized measure used to disseminate UV information to the public. Geographical and temporal changes in weighted UV are presented.

Solar UV Radiation and Its Transmission Through the Earth's Atmosphere

UV radiation is subdivided into three wavelength bands: UV-A (315–400 nm) radiation, UV-B (280–315 nm) radiation (some authors use 320 nm as the boundary between UV-A and UV-C radiation), and UV-C (100–290 nm) radiation. UV-A radiation is largely unaffected by ozone. UV-C comprises less than 0.6% of the incident solar spectrum at the top of the atmosphere, and it is effectively absorbed high in the Earth's atmosphere by oxygen (below ~240 nm) and by ozone (below 280 nm). UV-B radiation penetrates to the surface, but it is strongly absorbed by atmospheric ozone, whose

absorption cross-section increases rapidly towards shorter wavelengths in this spectral region. Consequently UV-B radiation received at the Earth's surface is highly variable and shows a strong dependence on solar zenith angle (SZA) and ozone amount (Table 1), leading to large geographical and temporal variabilities. As with other spectral regions of solar radiation, it is also modulated by other factors, as follows:

1. Variability in solar output. The greatest changes in solar output occur in UV-C radiation, which is not transmitted to the Earth's surface. Paradoxically, increases in solar output (e.g., associated with 27-day solar rotation, or the 11-year solar cycle) usually produce slight reductions in UV at the surface because they result in increased ozone production.
2. Seasonal differences in Sun–Earth separation. For a given solar zenith angle, irradiances in December and January will be approximately 7% larger than in June and July owing to the elliptical orbit of the Earth about the Sun.
3. Scattering and absorption in clouds. This generally reduces UV radiation at the surface, but under partly cloudy conditions with the Sun unobscured, significant increases are also possible.
4. Scattering and absorption by aerosols. This generally reduces UV radiation.
5. Rayleigh scattering by air molecules. This is much more important in the UV region than the visible region since it has a wavelength dependence.
6. Reflections from the surface. In the UV most natural surfaces have reflectivities (or albedo) less than 5%. However, fresh snow can have a reflectivity of >90%, leading to a greatly increased diffuse UV contribution.
7. Altitude. In unpolluted conditions, UV-B irradiance increases by approximately 5% per kilometer because of reduced Rayleigh scattering. This rate of increase can be increased appreciably when the effects of snow cover and boundary layer extinctions are included.

Because of its strong dependence on sun angle there are large seasonal variations in UV radiation, which become larger with increasing latitude. Seasonal and latitudinal variations in ozone are also important. Globally, the average total

Table 1 Approximate contributions (W m^{-2}) to solar energy from the UV-A and UV-B regions at 1 AU (cloudless skies, no aerosols; solar constant = 1370 W m^{-2})

Conditions	UV-B (280–315 nm)	UV-B (280–320 nm)	UV-A (315–400 nm)
Extraterrestrial	17.7	21.3	86.4
Earth surface, SZA = 0°, ozone = 300 DU	2.23	4.07	66.5
Earth surface, SZA = 60°, ozone = 300 DU	0.41	0.95	27.0
Earth surface, SZA = 60°, ozone = 450 DU	0.22	0.63	26.7
Earth surface, SZA = 60°, ozone = 100 DU	1.17	1.95	27.6

1 AU = 1 Astronomical Unit—the mean Earth–Sun separation.

ozone column amount is approximately 300 Dobson units ($1 \text{ DU} = 2.69 \times 10^{16} \text{ molecule cm}^{-2}$), with a normal range of around 250 to 450 DU. In recent years, there has been a significant reduction in ozone. Ozone column amounts below 100 DU have been observed in the Antarctic spring. However, they occur only at relatively large solar zenith angles, so although UV intensities have increased greatly, they usually remain moderate by global standards. The UV intensities are greater in the tropics, where noon time solar zenith angles are smaller and where total column ozone amounts tend to be smaller. The highest intensities occur at high altitudes (particularly over snow-covered surfaces) in the tropics, where losses by Rayleigh and aerosol scattering are minimized.

Exposure to UV Radiation

The human eye responds to light with wavelengths from about 790 nm (red) to 430 nm (violet). Ultraviolet (beyond-violet) wavelengths are shorter than the human eye 'sees'. Sunlight is received as direct rays and as diffuse light, i.e. skylight which has been scattered by the atmosphere. In the visible region the direct beam component dominates over the diffuse component whereas in the UV-B region, where scattering processes are more efficient, the diffuse component is usually dominant. The sky is blue because air molecules scatter the shorter-wavelength blue light more than the red light. UV radiation is scattered even more than blue light. If we could 'see' in the UV, the Sun would appear as a dull disk in a uniformly bright sky. Being shaded from the Sun's direct rays provides only partial protection from UV exposure because of the high level of diffuse UV light. In the visible region most natural surfaces have relatively high reflectivity, so that reflected light makes an important contribution, whereas in the UV region this is not the case.

Small doses of UV radiation are beneficial to humans, leading for example to the production of vitamin D. However, larger doses can be harmful, leading to ocular damage, immune suppression, and damage to the skin. Skin-damaging effects include ageing, erythema (skin reddening), sunburn, and some forms of skin cancer. For overhead sun conditions and for relatively low ozone amounts (e.g. in the tropics), damage to the most sensitive skin types can occur with exposures times of ~ 10 min.

Typical window glasses transmit less than 10% of sun-burning ultraviolet light, and sun block creams work by absorbing or reflecting UV rays. The SPF rating of sunscreens gives an indication of their effectiveness as UV blockers. For example, an SPF of 15 means that it should take 15 times as long before skin damage occurs as it would for damage to occur to unprotected skin (i.e., the cream, when correctly applied, should block $\sim 93\%$ of the radiation that causes skin damage).

Spectral Irradiance and UV Index

When the spectrum of UV radiation is examined in detail it becomes apparent that there are large variabilities within the broad categories discussed above. Typical clear sky spectra are shown in Figure 1(a) (note the logarithmic y-axis scale) for overhead sun assuming no ozone absorption, and for two solar

Figure 1 (a) Clear-sky spectra (at 1 AU) for no ozone and overhead sun (black), and for 300 DU ozone to represent the spectral irradiance that would be seen at solar zenith angles of 22.5° and 67.5° (red and blue respectively, corresponding to noon at midwinter and midsummer at a midlatitude site). The gray line is the erythemal action spectrum defined in the text, which is normalized to unity $\lambda \leq 298 \text{ nm}$ (unit less). (b) The spectra weighted by the erythemal action spectrum. Also shown are weighted irradiances for 100 and 450 DU. Corresponding values of the erythemally weighted UV Irradiance and UV Index are given.

zenith angles with 300 DU ozone. These two solar zenith angles correspond to noon time at midlatitudes in the summer and winter, and demonstrate that during the summer months midlatitude sites experience UV comparable to that in the tropics, but in winter the irradiances at midlatitudes are much less. At wavelengths less than 290 nm, absorption by ozone has reduced the irradiances by ~ 5 orders of magnitude. The detailed structure in the spectra is due principally to absorptions by gases in the solar atmosphere (Fraunhofer lines).

For many biological processes, the damaging effects of UV radiation become progressively more severe at shorter wavelengths. One commonly used weighting function to describe this effect is the so-called erythemal action spectrum for damage to human skin (Figure 1(a)). Spectra of erythemally weighted UV irradiances are shown in Figure 1(b). The peak contributions occur in the UV-B wavelength range, with the relative contribution from the UV-A becoming more important at larger SZA and larger ozone amounts. The weighted

irradiance for $\text{SZA} = 22.5^\circ$ are nearly a factor of 10 more than for $\text{SZA} = 67.5^\circ$, a difference much larger than if the ozone is changed from 300 DU to 450 DU. The curve for $\text{SZA} = 67.5^\circ$, ozone = 100 DU gives an indication of the weighted irradiance under the Antarctic ozone hole conditions. With this extremely low ozone amount there is a shift in the peak to shorter wavelengths.

Information on UV intensities is disseminated to the public in terms of the erythemally weighted UV irradiance (Figure 1(b)). The erythral weighting function applied to the spectrum involves an arbitrary normalization to unity at wavelengths shorter than 298 nm, so erythemally weighted UV is not strictly defined in terms of an SI unit. Furthermore, when UV information is provided to the public, another normalization is applied to provide a number, called the UV Index. Historically, the reason for this normalization choice was to give a maximum UV Index of about 10 in Canada, where the unit was first used.

$$\text{UV Index} = 40 \int I(\lambda)w(\lambda)d\lambda$$

where λ is the wavelength in nm, $I(\lambda)$ the irradiance in W m^{-2} , and $w(\lambda)$ the erythral weighting function defined (Figure 1(a)) as:

$$\begin{aligned} w(\lambda) &= 1.0 && \text{for } 250 < \lambda \leq 298 \text{ nm;} \\ w(\lambda) &= 10^{0.094(298-\lambda)} && \text{for } 298 < \lambda \leq 328 \text{ nm;} \\ w(\lambda) &= 10^{0.015(139-\lambda)} && \text{for } 328 < \lambda \leq 400 \text{ nm;} \\ w(\lambda) &= 0 && \text{for } \lambda > 400 \text{ nm.} \end{aligned}$$

While there may be uncertainties about the biological applicability of this erythral action spectrum, its great advantage is that it is mathematically defined and therefore its detailed shape is unambiguous. This is important in the UV region, where the steeply sloping spectrum spans several orders of magnitude (Figure 1(a)). Although the UV Index was developed to represent damage to human skin, it may be applied to other processes, since many biological UV effects have similar action spectra.

In reality, the UV Index is an open-ended scale, and outside the protection of the Earth's atmosphere the UV Index is ~ 300 (depending on the lower wavelength limit of the integration). Table 2 shows how the UV Index varies as a function of ozone and solar zenith angle. When applying this table to geographic regions, it is also necessary to apply corrections for variations in Sun–Earth separation.

Sensitivity of UV to Ozone Change

The sensitivity of UV radiation to atmospheric ozone is sometimes expressed as a so-called radiation amplification factor (RAF), defined as

$$\text{RAF} \equiv (\delta R/R)/(-\delta \Omega/\Omega)$$

where R and δR are, respectively, the dose rate (i.e., irradiance) and its change when the ozone column Ω changes by a small amount $\delta \Omega$.

For larger changes it is more accurate to use a power-law formulation:

$$R_2/R_1 = (\Omega_2/\Omega_1)^{-\text{RAF}}$$

where R_1 and R_2 are the dose rates for ozone columns Ω_1 and Ω_2 respectively.

The RAFs for several action spectra and weighting of UV radiation, computed for clear skies, are shown in Table 3 (processes with small RAFs are omitted).

Global and Regional Patterns

Estimates of UV irradiance are available from direct measurements at the surface, or from model calculations. In recent years satellite measurements of ozone have been used in conjunction with satellite-derived cloud parameters (e.g., reflectances) to estimate UV irradiances and UV dosage at the Earth's surface. For example, Figure 2 shows a global mean annual climatology of erythral UV dose, including cloud effects based on 14 years of measurements between 1979 and 1992 from the Total Ozone Mapping Spectrometer (TOMS) instrument on the NIMBUS-7 satellite. The largest doses occur at the Equator, particularly in cloud-free and high altitude regions. In polar regions, the mean daily doses are small because of the low Sun elevations experienced at these locations. However, during the period of the springtime ozone hole, UV doses in Antarctica can be comparable to those at midlatitudes.

While these global products have been validated at a few locations, the sensors used do not sample radiation from the boundary layer. Consequently, a constant extinction by tropospheric aerosols is often assumed, so the products are unable to resolve differences due to variation in tropospheric pollution. For example, during summer months the UV measured at the surface in unpolluted Southern Hemisphere

Table 2 UV Index as a function of ozone and SZA at 1 AU (altitude 0.00 km, aerosol optical depth 0.00, albedo 0.05)

Ozone (DU)	Solar zenith angle (°)

Damage to cornea of the eye	1.2	1.1
Damage to lens of the eye (cataract)	0.8	0.7
Immune suppression damage	1.0	0.8
UV-A (315–400 nm)	0.03	0.02
UV-B (290–315 nm)	1.25	0.99
UV-B (290–320 nm)	0.87	0.71

**Figure 2** Global mean daily UV erythemal dose, including cloud effects from a 14-year climatology of ozone 1979–92. Data from the National Center for Atmospheric Research, USA.**Figure 3** World clear sky UV Index at midday for 5 October 2000. Data from the Australian Bureau of Meteorology.

Figure 4 Sample map of noon time UV Index including cloud effects over the Australian region for December 1996. H and L refer to local maxima and minima. Data from the Australian Bureau of Meteorology.

sites is approximately 40% greater than at equivalent latitudes in Europe, whereas the differences derived from satellite observation appear closer to the 15% expected from differences in ozone and Sun–Earth separation. Daily estimates of UV doses are available on the internet.

In several countries, agencies provide UV Index information to the public either through the media, or through direct internet access. The UV Index is calculated with radiative transfer models using measured ozone fields (usually from satellite observations). An example of a global map of the clear-sky UV index is shown in Figure 3. This model includes estimates of the effects of topographical variations, leading to local UV maxima in high-altitude regions. The map shown is from 5 October 2000, a period when the Antarctic ozone hole was weakening and was displaced towards South America, bringing enhanced UV radiation to that sector.

For the purposes of providing forecasts of UV Index for the next day, some agencies include refinements to advect ozone fields and to include estimates of the modulation by clouds. At this stage, products of this type appear to be available on a regional basis only (e.g. Figure 4).

For the purposes of reporting the time evolution of UV Index from the previous day, calculated values can be compared with observations at selected sites. A sample of this is shown in Figure 5. This plot shows how the presence of clouds can increase or decrease the instantaneous UV irradiances. The morning was overcast, resulting in reduced UV irradiances.

Figure 5 Measured UV Index at Lauder, Central Otago, New Zealand, 9 January 2000, compared with predictions from a clear-sky model using ozone from the NOAA Tiros Operational Vertical Sounder (TOVS) instrument. Data from the National Institute for Water and Atmospheric Research, New Zealand.

During the period when the clouds cleared around midday, there were large departures about the clear-sky predictions in both senses. This was followed by a period of several hours in the afternoon when there was good agreement between the clear-sky model and the measurements.

Figure 6 Mean ozone (a) and estimated UV Index (b) at Lauder, New Zealand, for summers from the summer of 1978–79 through the summer of 1999–2000. Summer is defined as the period from December through February. The solid line in (a) shows the changes in summertime ozone that have occurred since the 1970s. The solid line in (b) shows the deduced changes in clear-sky UV expected from these changes in ozone. The symbols (from 1989–90 on) show measured values of ozone and the summertime peak UV Index, both derived from the UV spectroradiometer. The error bar shows the estimated uncertainty in measurement. Adapted from McKenzie RL, Connor BJ and Bodeker GE (1999) Increased summertime UV observed in New Zealand in response to ozone loss. *Science* 285: 1709–1711.

Long-Term Trends

Since satellite observations of ozone began, significant decreases in ozone amounts have been observed outside the tropical region. These have been most pronounced at high latitudes, particularly in the Southern Hemisphere. Prior to 1990, there were few reliable long-term measurements of UV

available. Since then there has been a rapid growth in instrument development and deployment. These instruments range from those that continuously monitor weighted UV irradiances at low spectral resolution through to scanning spectrometers which acquire UV irradiances at spectral resolutions less than 1 nm. However, because of the difficulties of maintaining instrumentation to measure UV with sufficient accuracy, and because of natural variability in cloud cover, there have been few measurements which have clearly demonstrated the expected increases in UV radiation resulting from ozone depletion. Usually it is necessary to restrict the data set to demonstrate the increases in UV due to ozone while suppressing the variability due to clouds. **Figure 6** shows one example to illustrate the long-term reductions in ozone and the attendant changes in peak summertime erythral UV that have occurred at a clean site in New Zealand (45° S).

Synopsis

Because aerosols vary on many spatial and temporal scales and exhibit a diversity of environmental impacts, satellite remote sensing makes an essential contribution to the study of airborne particles. Since the very first orbiting imagers began observing Earth, the scope of satellite data products has provided inspiration, qualitative indications, and, increasingly, quantitative constraints on the regional and global influences that aerosols exert. Major advances in this field have taken place in the last decade, providing better constraints on atmospheric processes, short-term forecasting, and climate modeling. Further advances can be expected from greater integration of satellite and suborbital data with models.

Dedication: This article is dedicated to the memory of Dr Yoram J. Kaufman, who coauthored the entry for *Satellite Remote Sensing: Aerosol Measurements* in the previous edition of this Encyclopedia. Yoram's many creative ideas greatly enriched this field, and his untimely passing in June 2006 was a great loss to our community.

Introduction

Aerosols are solid or liquid particles suspended in the air, and those observed by satellite remote sensing are typically between about 0.05 and 10 μm in size. (Note that in traditional aerosol science, the term 'aerosol' refers to both the particles and the medium in which they reside, whereas for remote sensing, the term commonly refers to the particles only. In this article, we adopt the remote-sensing definition.) They originate from a great diversity of sources, such as wildfires, volcanoes, soils and desert

sands, breaking waves, natural biological activity, agricultural burning, cement production, and fossil-fuel combustion. They typically remain in the atmosphere from several days to a week or more, and some travel great distances before returning to Earth's surface via gravitational settling or washout by precipitation. Many aerosol sources exhibit strong seasonal variability, and most experience interannual fluctuations. As such, the frequent, global coverage that space-based aerosol remote-sensing instruments can provide is making increasingly important contributions to regional and larger-scale aerosol studies.

Aerosols affect Earth's energy balance through direct radiative forcing – scattering sunlight back to space, which increases the top-of-atmosphere (TOA) albedo over most surfaces, producing net surface cooling. Darker particles absorb some incoming light, warming the ambient atmosphere, changing cloud properties locally, and possibly altering regional atmospheric circulation patterns. Aerosols also exert 'indirect' effects on clouds, as they provide cloud condensation nuclei and ice

nuclei essential for cloud particle formation, and can thus mediate cloud microphysical properties and regional water cycles. In addition, the near-surface aerosol concentration is a factor affecting local air quality. Many of these topics are explored elsewhere in this Encyclopedia (*see Aerosols: Climatology of Tropospheric Aerosols; Aerosol Physics and Chemistry; Role in Radiative Transfer; Aerosol–Cloud Interactions and Their Radiative Forcing; Satellites and Satellite Remote Sensing: Precipitation*).

The current article focuses on what has been and can be learned about aerosols from space-based remote sensing. Compared to the much older field of *in situ* aerosol sampling, satellite remote sensing is a blunt object, offering at present snapshots of the horizontal and vertical distribution of aerosol amounts over land and water, typically at horizontal spatial resolution of several kilometers, and loose classification of aerosol type under favorable retrieval conditions. Its essential contribution is the scope of coverage, which, even in the early days of satellite imagery in the 1960s, helped establish the transcontinental mineral dust pathway from the North African desert to the Caribbean (**Figure 1**), and has since provided regional and global contexts for a broad range of leading climate and health-related aerosol questions. More recently, advanced passive imagers and active lidar systems have been flown successfully in space; we tell their story here.

Aerosol Remote Sensing over Oceans

Two of the main challenges for satellite aerosol remote sensing are (1) separating the surface from the atmospheric contributions to the TOA observations, and (2) identifying the light-scattering properties of the particles, which are related to aerosol type. The first of these is dramatically reduced where satellite aerosol retrievals are performed over dark, uniform water surfaces, so early efforts to retrieve aerosol column amounts from space were performed over oceans.

Advanced Very High-Resolution Radiometer, Sea-Viewing Wide Field-of-View Sensor, and Geostationary Satellites

From a single red-band spectral channel centered at 0.63 μm , where the ocean surface tends to be dark, together with an assumed optical model for the particles involved, estimates of total-column aerosol amount were derived from Advanced Very High-Resolution Radiometer (AVHRR) reflectance measurements. These revealed the seasonal patterns of major dust, smoke, and pollution aerosol plumes on a global scale (**Figure 2**), providing both inspiration for improved aerosol measurement and modeling, and some actual constraints on chemical transport models that aimed at simulating, and to some extent predicting, the environmental impacts of airborne particles. AVHRR instruments began collecting continuous data from space in 1981, and they offer a substantial time series of global aerosol distributions. Some more recent algorithms incorporate a second AVHRR spectral channel, making it possible to derive limited particle size constraints. But poor radiometric calibration accuracy and the small number of relatively broad spectral bands on these wide-swath, single-

view instruments limited the quantitative application of the data to aerosol research. Similar products related to aerosol amount have been derived with higher temporal resolution from the US National Oceanic and Atmospheric Administration's (NOAA) Geostationary Environmental Satellites (GOES), the European Space Agency's (ESA) Spinning Enhanced Visible and Infrared Imager (SEVIRI) geostationary instrument, and also the US National Aeronautics and Space Administration's (NASA) polar-orbiting Sea-viewing Wide Field-of-view Sensor (SeaWiFS), a space-based multispectral imager that has much narrower and better-calibrated spectral bands than the AVHRR.

MODerate-Resolution Imaging Spectroradiometer

Whereas the intensity of sunlight reflected by aerosols is closely related to column amount, the spectral dependence of the aerosol-reflected component contains some information about particle size. The MODerate-resolution Imaging Spectroradiometers (MODIS), part of the NASA Earth Observing System (EOS), represents a second generation of multispectral imagers, having 36 spectral channels spanning 0.4–14.4 μm , high radiometric calibration accuracy and stability, and subkilometer pixel resolution. These features make it possible to produce a significantly higher quality constraint on the optically equivalent aerosol column amount, generally reported as the extinction aerosol optical depth (AOD), a measure of the amount of light removed from an incident beam at a given wavelength, due to scattering in all directions as well as absorption by particles. The first MODIS instrument was launched with the EOS *Terra* satellite and began acquiring data in early 2000; a second MODIS began its mission on EOS *Aqua* in June 2002. Over the ocean, MODIS TOA, scattered-light measurements from six visible and near-infrared spectral channels are interpreted in terms of AOD and fine-mode AOD fraction (FMF), along with estimates of the fine- and coarse-mode effective sizes, providing global coverage approximately every 2 days (**Figure 3**). A standard dark ocean surface model is assumed, including sun-glint exclusion and wind-dependent whitecap reflectance, and particle properties are selected from a predetermined list of likely aerosol types. The FMF is helpful in identifying aerosol type, as mechanically produced desert dust and maritime aerosols formed by breaking waves tend to be dominated by 'coarse-mode' particles larger than a micron in diameter, whereas the populations of smoke, pollution, and other combustion and biogenic aerosols fall largely into the submicron 'fine mode.'

Over-Ocean AOD Trends and the Visible Infrared Imaging Radiometer Suite

One important application of the regional- to global-scale AOD time series derived from satellite observations has been the identification of trends. Aerosol amounts vary on many spatial and temporal scales, so determining systematic tendencies requires relatively long, high-precision data records, having sufficient spatial coverage and temporal frequency to account for measurement anomalies and isolated events such as volcanic ash and wildfire smoke plumes.

Figure 1 (a) Trajectory of a Saharan dust plume, tracked over 8 days from the source region in North Africa across the Atlantic Ocean to the Caribbean, based on images from a wide-swath vidicon camera aboard the polar-orbiting ESSA 5 satellite. (b) ESSA 5 satellite image of the plume (indicated by white arrow) over Mauritania, the western Sahara Desert, and the eastern Atlantic on 7 June 1967. Dust particles more than $20\ \mu\text{m}$ in diameter from this storm were recovered subsequently in Barbados. Reproduced from Prospero, J.M., Bonatti, E., Schubert, C., Carlson, T.N., 1970. Dust in the Caribbean atmosphere traced to an African dust storm. *Earth Planetary Science Letters* 9, 287–293.

Such analysis was first performed with 25 years of AVHRR data and subsequently, with the first decade of carefully filtered MODIS AOD retrievals (Figure 4). The globally averaged over-ocean trend derived between 2000 and 2009 was negligible, but some significant regional AOD increases and smaller decreases were found, in most cases traced to changes in human activity. To continue this time series, a broad-swath, multispectral Visible Infrared Imaging Radiometer Suite (VIIRS) imager, having capabilities in some

respects similar to those of MODIS, was launched on the National Polar-orbiting Operational Environmental Satellite System Preparatory Project (NPP; now the Suomi National Polar-orbiting Partnership, or Suomi NPP) satellite in 2011, the first in a series planned for future NOAA operational polar-orbiting satellites.

Retrieving AOD over land with comparable accuracy from space-based observations is more difficult, but significant progress has been made in this area as well.

Figure 2 Global, over-ocean estimates of total-column aerosol amount for the northern (a) winter and (b) summer seasons, derived from 2 years (July 1989–June 1991) of midvisible reflectance measurements from the Advanced Very High-Resolution Radiometer (AVHRR) instruments aboard NOAA polar-orbiting satellites. The winter peak in grassland burning produces a smoke plume over the Atlantic Ocean west of the Sub-Saharan region, whereas in summer, dust from North Africa and smoke from Central Africa produce plumes over the adjacent water, and dust from the Middle East blankets the Arabian Sea. Pollution sources off the east coast of China vary little between these two seasons, whereas pollution off the east coast of the United States is more prominent in summer. Reproduced from Husar, R.B., Prospero, J.M., Stowe, L.L., 1997. Characterization of tropospheric aerosols over the oceans with the NOAA advanced very high resolution radiometer optical thickness operational product. *Journal of Geophysical Research* 102, 16889–16909.

Figure 3 MODIS global monthly average aerosol products for July 2010. (a) AOD from the combination of Dark Target and Deep Blue algorithms; and (b) fine-mode fraction (FMF) over ocean, with AOD, related to the confidence with which FMF can be determined, encoded as the saturation of the color applied, and all derived with the Dark Target algorithm. Provided by the MODIS Team, NASA Goddard Space Flight Center.

Aerosol Remote Sensing over Land

The land surface of Earth is generally brighter and more variable than that of the ocean. To retrieve aerosol amount and type over land from satellite observations, the typically

smaller aerosol-reflected component of upwelling radiation must be distinguished from the surface-reflected component. Since the early days of satellite aerosol observation, a range of approaches has been conceived, developed, and applied to address this challenge.

Figure 4 Global and regional, over water: (a) midvisible AOD trends, and (b) associated confidence levels, derived from 10 years (2000–09) of MODIS operational aerosol products. The MODIS time series was first filtered to remove outliers and reduce possible cloud contamination, and was calibrated using less frequent but more accurate MISR and AERONET observations. Confidence levels were assessed as the derived trend (ω), normalized by the estimated time series standard deviation (σ_ω), on $1^\circ \times 1^\circ$ grid cells. Increasing AOD trends are found over the Bay of Bengal, east coast of Asia, and Arabian Sea, whereas weaker AOD decreases were derived from Central America, the east coast of North America, and the west coast of Africa. Reproduced from Zhang, J., Reid, J.S., 2010. A decadal regional and global trend analysis of the aerosol optical depth using a data-assimilation grade over-water MODIS and Level 2 MISR aerosol products. *Atmospheric Chemistry and Physics* 10, <http://dx.doi.org/10.5194/acp-10-1-2010>.

Total Ozone Mapping Spectrometer Instruments and the Ozone Mapping Instrument

Atmospheric gas molecules scatter ultraviolet (UV) light very efficiently, partly obscuring the surface as viewed from space, and Earth's surface tends to be darker in UV light than in visible light. So the differential absorption in two UV spectral channels from the Total Ozone Mapping Spectrometer (TOMS) instruments, which began taking data in 1979, and subsequently from the Ozone Mapping Instrument (OMI), has been interpreted as an Aerosol Index, a qualitative measure of aerosol

amount over land and water. With some assumptions and constraints on aerosol vertical distribution and on aerosol UV absorption properties (usually represented by the single-scattering albedo (SSA), which is the ratio of the fraction of light scattered to that scattered and absorbed by the particles at a given wavelength), these data also yield the AOD (Figure 5). As the retrieval is based on aerosol absorption of the upwelling UV radiation, it tends to be less sensitive to near-surface aerosol. A similar approach was used for the European Global Ozone Monitoring Experiment (GOME) satellites.

Figure 5 TOMS aerosol data products. (a) Aerosol index (AI) map over South and Southeast Asia and surrounding water, for 13 April 2001. Dust over Central Asia, smoke and pollution aerosol over Southeast Asia, and dust combined with pollution over East-Central Asia stand out. Reproduced from Hsu, N.C., Herman, J. R., Bhartia, P. K., Seftor, C. J., Torres, O., Thompson, A. M., Gleason, J. F., Eck, T. F., Holben, B. N., 1996. Detection of biomass burning smoke from TOMS measurements. *Geophysical Research Letters* 23, 745–748. (b) Zonal-average AOD time series at 380 nm, covering 1979–92 and 1996–2000. Note the prominent volcanic plumes from El Chichon in 1982 and Mt. Pinatubo in 1991, each lasting many months. MODIS Dark Target, Deep Blue, and Multiangle Implementation of Atmospheric Correction

Several approaches have been used to obtain AOD over land from the MODIS instruments. The Dark Target method over land relies on the 2.1 μm MODIS channel, in which atmospheric gas and aerosol opacity are generally low, to provide a constraint on the surface reflectance. An empirical relationship is then used to extrapolate the surface reflectance to visible wavelengths, where the AOD is determined; a similar approach is used for the ESA's Medium Resolution Imaging Spectrometer (MERIS) and is planned for the next generation of US geostationary satellite multispectral imagers. Over land, the aerosol type used in the algorithm is assumed, based on climatology derived from the global Aerosol Robotic Network (AERONET) of surface sun and sky-scanning photometers (Figure 6). AERONET also provides high-quality AOD measurements used to validate many satellite AOD products. As MODIS also has a relatively short-wavelength Deep Blue

channel at 0.41 μm , a variant of the UV absorption technique provides AOD from that instrument over brighter surfaces, such as desert. The combination of MODIS's dark water, Dark Target land, and Deep Blue AOD products is illustrated in Figure 3(a). A third approach for extracting AOD over land from MODIS is called Multiangle Implementation of Atmospheric Correction (MAIAC). It relies on detecting temporal variations in the observed radiance. The changing AOD, Ångström exponent (i.e., the spectral dependence of the AOD; specifically, minus the spectral slope of AOD in log-log coordinates), and surface angular reflection properties are extracted from 16-day time series of MODIS imagery, capturing multiple views of the region at different angles.

Along-Track Scanning Radiometer-2 and Multiangle Imaging SpectroRadiometer

As Earth is viewed at steeper angles, the atmospheric contribution to the TOA reflectance systematically increases, and the

Figure 6 Averaged particle spectral single-scattering albedos (SSA) and size distributions for several sites dominated by pollution, smoke, dust, and oceanic aerosols, as derived from AERONET surface-based sun photometer measurements. AOD at 440 nm for the cases shown are indicated as τ_{440} ; the real part of the particle refractive index is given as n , and the spectral dependence of the AOD (Ångström exponent), evaluated at 440 and 870 nm, is designated α . Note how the size distributions vary with aerosol type, and how SSA varies considerably even within the urban-industrial and biomass-burning categories. Reproduced from Dubovik, O., Holben, B.N., Eck, T.F., Smirnov, A., Kaufman, Y.J., King, M.D., Tanré, D., Slutsker, I., 2002. Variability of absorption and optical properties of key aerosol types observed in worldwide locations. *Journal of Atmospheric Science* 59, 590–608.

surface is increasingly obscured. Multiangle observations make it possible to separate surface from atmosphere based on the varying air mass factors through which the observations are made. The ESA's Along-Track Scanning Radiometer-2 (ATSR-2) imagers made use of this approach with a two-angle configuration beginning in 1995; and in 2000, the NASA EOS's Multiangle Imaging SpectroRadiometer (MISR), with nine cameras pointed at angles ranging from 70° aft, through nadir, to 70° forward along the orbit track, began operations. The AOD over land and ocean is produced from both ATSR-2 and MISR instrument data sets; ATSR also reports the Ångström exponent, and MISR provides a classification of aerosol 'type' under favorable retrieval conditions, based on loose aerosol size, shape, and SSA constraints that can be derived from the multiangle, multispectral data (Figure 7).

POLarization and Directionality of the Earth's Reflectances

Polarization is an additional property of light from which information about a scene can be extracted. The inclusion of polarization sensitivity with multispectral, multiangle

capabilities allows the French Space Agency's (CNES) POLarization and Directionality of the Earth's Reflectances (POLDER) series of imagers to retrieve fine-mode and total AOD over land and water. The analysis takes advantage of the relative spectral independence of polarized reflectance for most land surfaces, and the greater polarization of light scattered by smaller and more spherical particles, such as smoke or pollution, compared to larger, nonspherical desert dust. The POLDER instruments began acquiring data in 1997, and they combine spectral, angular, and polarization information to monitor aerosol (Figure 8).

Particle Properties

In general, having constraints on particle properties improves the accuracy of AOD results for both the UV absorption and the various scattering retrieval techniques. Knowing the aerosol type is also critical for source attribution, the assessment of aerosol radiative forcing, the determination of material fluxes, and other applications that depend upon knowing the chemical or physical nature of the particles. So in addition to the multispectral

Figure 7 MISR (a) true-color, nadir-viewing image of a Sahara Desert dust plume over the Atlantic Ocean north and east of the Cape Verde Islands (which are visible in the center of the image); and retrieved (b) AOD, (c) Ångström exponent, and (d) fraction AOD nonspherical. North is roughly toward the top of the images, and the swath is about 380 km wide. The plume has higher AOD, and the dust particles are larger (i.e., a smaller Ångström exponent) and more nonspherical compared to background values. Provided by the MISR Team, NASA Goddard Space Flight Center and Jet Propulsion Lab/Caltech.

Figure 8 Three-month (September through November), global fine-mode AOD at 550 nm over land and water, derived from POLDER observations: (a) averaged over 5 years (2005–09); and (b–f) AOD anomaly for each individual year. Blue in the anomaly panels indicates that the AOD for that year was lower than the longer-term mean, whereas red indicates higher values. Note the high interannual variability in the biomass-burning regions of Brazil, Southern Africa, Indonesia, and the northern boreal latitudes. Adapted from Tanré, D., Breon, F.M., Duzé, J.L., Dubovik, O., Ducos, F., Francios, P., Goloub, P., Herman, M., Lifermann, A., Waquet, F., 2011. Remote sensing of aerosols by using polarized, directional and spectral measurements within the A-Train: the PARASOL mission. *Atmospheric Measurement Techniques* 4, 1383–1395, <http://dx.doi.org/10.5194/amt-4-1383-1395-2011>.

assessment of particle size, and the multiangle multispectral determination of particle type with and without polarization, several other techniques for constraining properties from space have been demonstrated, at least on a case-by-case basis.

The *critical reflection* technique relies on the idea that if particles reflect more light at a given view angle and wavelength than the surface below, the TOA reflectance will increase with AOD, whereas if the particles reflect less light than the surface below, the TOA reflectance will decrease as AOD increases. So if a layer of aerosol that is uniform in amount and type overlies a surface of varied albedo, some parts of the scene will be brightened more than others by the aerosols. From images of the scene on several days when the aerosol type is similar but the AOD is different, the SSA of the particles can be deduced. As aerosol properties for a given source in a given season tend to be repeatable, even if the amount of aerosol varies considerably, this is a credible approach for deriving aerosol type information over variable land surfaces in some locations.

Other methods combine the capabilities of several instruments to help constrain underdetermined remote-sensing retrievals. For example, the TOMS and OMI UV AOD retrievals are sensitive to particle SSA and aerosol vertical distribution, and pixels several tens of kilometers in size from these instruments can be affected by undetected subpixel clouds. Combining TOMS or OMI observations with near-coincident MODIS AOD and relatively high-spatial-resolution cloud clearing can produce more accurate

constraints on SSA. When aerosol vertical distribution from an active sensor such as the NASA EOS's Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) (Figure 9) is included, even tighter constraints can be derived on aerosol properties and scene conditions. Similarly, data from the two-angle-viewing AATSR, providing AOD and cloud identification at relatively high spatial resolution, have been combined with high-spectral-resolution observations from the SCanning Imaging Absorption spectroMeter for Atmospheric CHartographY (SCIAMACHY), both aboard ESA's Envisat, to distinguish mineral dust, sea salt, soot, and water-soluble aerosol types.

With recent technological advances and the demonstrated value of multiangle, multispectral, polarizing imagery covering UV through visible into near-infrared light, future satellite aerosol instruments will likely combine all these capabilities into a single passive, broad-swath, remote-sensing imager.

Constraints on Climate Models

Synthesizing the collection of observations into a global picture while taking account of the relative strengths, limitations, and gaps in the various data records is a challenge in itself. But it is an essential step in applying the measurements to short-term forecast models and to long-term climate models, which are

Figure 9 CALIPSO vertical profiles. (a) Backscatter curtain plot, showing cloud and aerosol layers over the region highlighted in dark blue in the adjacent context map. Spectral and depolarization lidar signals identify transported dust (yellow arrow) overlying a surface layer of polluted continental aerosol (red arrow). Clean maritime aerosol and maritime aerosol mixed with dust and pollution particles (cyan arrow) are found farther south along the orbit track. (b–e) Seasonally aggregated dust (orange) and nondust, mainly smoke and pollution (blue) vertical extinction profiles over eastern China in 2007. Note how the vertical extent is a minimum in the autumn (SON) and winter months (DJF), and that the dust amount peaks in the winter and spring (MAM) seasons. The total-column AOD (τ_c) and effective aerosol scale height (H_e) are indicated in each panel. Reproduced from Yu, H., Chin, M., Winker, D.M., Omar, A.H., Liu, Z., Kittaka, C., Diehl, T., 2010. Global view of aerosol vertical distributions from CALIPSO lidar measurements and GOCART simulations: regional and seasonal variations. *Journal of Geophysical Research* 115, D00H30, <http://dx.doi.org/10.1029/2009JD013364>.

the primary tools for diagnosing many atmospheric processes and for making predictions. One approach has been to assimilate the observations into models, ‘nudging’ the model AOD based on available measurements. The frequent (1- to 2-day) global coverage of the MODIS AOD data has been successfully used to improve several-day AOD model forecasts, once the satellite data set was filtered to remove outliers and retrievals that might have been affected by unscreened cloud, leaving about 50% of the original points.

For longer-term climate modeling, more uniform global products are generally required. Monthly, global maps of AOD were created from the combination primarily of MODIS, MISR, and surface sun photometer AERONET data. These are being used to constrain leading numerical climate models. In this case, the frequent coverage of MODIS over water, the approximately once-weekly but generally more accurate overland AOD from MISR, and the AERONET data (which are the most accurate but provide only spot sampling) were the main components aggregated into a unified AOD product (Figure 10).

Knowing aerosol vertical distribution is especially important for climate modeling, as aerosol reflection and absorption of sunlight at different levels in the atmosphere not only alter the surface energy budget but can also affect the atmospheric

stability structure, regional-scale atmospheric circulation, and aerosol impacts on clouds. The vertical distribution is also critical for assessing aerosol transports, as aerosols residing above the atmospheric boundary layer tend to stay aloft longer, travel farther, and have greater environmental impact. The CALIPSO lidar generates a curtain of backscatter profiles at two wavelengths and has polarization sensitivity, with up to about 330 m horizontal resolution and 30 m vertical resolution. Some vertically resolved aerosol type classification is also possible with these data. Coverage is limited to the width of the lidar beam, which means that most aerosol sources are missed, but the great sensitivity of the observations to very thin aerosol layers far downwind of sources provides accurate snapshots that can be aggregated into general climatological constraints (Figure 9(b)–(e)).

Aerosols are usually introduced into models by providing an inventory of *injection heights*, *source strengths*, and locations for different aerosol types. Aerosol injection heights, derived from the parallax in multiangle imaging views of aerosol plumes, can provide such information (Figure 11). Unlike lidar, stereo imaging requires aerosol plumes to exhibit discrete features that can be tracked in multiple angular views, so the technique applies mainly within a few hundred kilometers of

Figure 10 Maps of multiyear, annual-average, midvisible aerosol optical depth (AOD) from multiple remote-sensing data sets. A ‘synthesis’ of these AOD products (S^*), primarily from MISR, MODIS, and AERONET, used extensively for model validation, is highlighted in red. The global-average AOD for each data set is given below its label. Mi, MISR; Mo, MODIS land and water; Mn, MODIS over-ocean; Po, POLDER; To, TOMS; An, Ag, AVHRR (one- and two-channel retrieval algorithms, respectively); and Ae, AERONET ground-based sun photometer network. Reproduced from Kinne S., Schulz, M., Textor, C., Guibert, S., et al., 2006. An AeroCom initial assessment – optical properties in aerosol component modules of global models. *Atmospheric Chemistry and Physics* 6, 1815–1834.

major aerosol sources such as wildfires, volcanoes, and places where desert dust storms form. As a result, the lidar and stereo-imaging techniques are complementary; as aerosols tend to travel in discrete layers, the upwind injection heights from multiangle imaging and downwind layer heights from space-based lidar combine to provide powerful constraints on model simulations of aerosol vertical distribution.

Efforts to determine aerosol source strength from satellite observations all involve tight coupling between the available measurements and the aerosol transport models themselves. The inverse modeling approach takes the observed AOD distribution over a wide area and, in effect, runs the model backward to derive the sources. An alternative method involves running the model forward for a range of assumed source strengths and whatever constraints on injection height are available, and determines which assumed values best match the observed snapshot of AOD spatial distribution at the appropriate time step. Both methods have been demonstrated for individual cases (Figure 12), motivating continuing work to generalize these results.

One of the main applications for which frequent, global satellite aerosol observations are required is direct aerosol radiative forcing, the net change in energy flux (e.g., in W m^{-2}) at the surface produced directly by aerosol scattering and absorption. Uncertainty in the amount of surface cooling that aerosols produce is a limiting factor in determining the ability of climate models to predict changes in global mean surface temperature. Given the accuracy with which the radiative warming of long-lived greenhouse gases can be calculated, the required accuracy on aerosol properties to bring this factor into line is quite stringent. It is estimated that instantaneous, mid-visible AOD measurements need to be accurate to about 0.02 over much of the globe. Current capabilities are of the order of 0.05 or 20% of AOD, whichever is larger, over land, and somewhat better over dark water. Some improvement is expected as the algorithms used for current operational instruments are refined, but a substantial advance will likely require a next-generation space-based instrument, combined with better constraints on particle microphysical properties that will probably require a systematic program of aircraft and

Figure 11 Satellite views of the station fire that burned in the Los Angeles, California, area in late August and early September 2009. (a) True-color image from the MISR nadir-viewing camera on 30 August 2009, showing smoke plumes from multiple active fires, and an arc-shaped cloud upwind of the fire front, possibly formed by incoming air forced to rise over the buoyant air mass heated by the fires. Pyrocumulus clouds, formed over several highly convective spots in the burning region, appear as small white dots above the smoke plume. (b) MISR stereo-derived plume heights, reported as values above sea level, for individual pixels 1.1 km in size. surface-based direct sampling along with continued surface-based remote sensing (such as AERONET).

Applications to Cloud Formation and Air Quality

One of the most challenging questions to which satellite observations have been applied is assessing aerosol impacts on clouds, often called aerosol ‘indirect’ effects, as distinct from the direct radiative forcing that aerosols produce. Aerosols are essential for cloud droplet and ice particle formation, and they

serve as collection sites for water molecules, referred to as cloud condensation nuclei (CCN) and ice nuclei (IN), respectively.

Aircraft instruments are generally best suited to study indirect effects in detail, as they can sample the tens-to-hundreds-of-meters spatial scales and minutes-to-hours temporal scales that capture the cloud development process. Nevertheless, satellite instruments have a contribution to make, taking advantage of the frequent global coverage they offer, for exploring larger-scale patterns. With imaging from passive remote sensing, cloud albedo, cloud droplet radius, and cloud optical depth can be mapped, along with cloud top

Figure 12 Characterizing aerosol source strength. (a) Average of daily global MODIS fine-mode AOD maps covering 18–30 August 2000. Retrieving global aerosol sources from satellites using inverse modeling. *Atmospheric Chemistry and Physics* 8, 209–250. (c–j, second row) Successive panels showing a MODIS-visible image of a Siberian wildfire smoke plume on 20 July 2006; a MODIS-retrieved AOD snapshot from the standard product at 10 km spatial resolution; MODIS AOD averaged to the GOCART model $1^\circ \times 1.5^\circ$ grid; and AOD snapshots taken at the MODIS overpass time from five GOCART model runs, each initialized with different, commonly used parameterizations for smoke source strength. For wildfires in different biomes around the globe, different initialization choices performed systematically better compared to the corresponding MODIS observations. Reproduced from Petrenko, M., Kahn, R.A., Chin, M., Soja, A., Kucsera, T., Harshvardhan, 2012. The use of satellite-measured aerosol optical depth to constrain biomass burning emissions source strength in the global model GOCART. *Journal of Geophysical Research* 117, D18212, <http://dx.doi.org/10.1029/2012JD017870>.

temperature and pressure, aerosol amount, and aerosol type. However, typical CCN populations are skewed toward particle sizes that remote-sensing techniques cannot distinguish from atmospheric gas molecules. So efforts have been made to identify proxies derived from those parts of the aerosol size spectrum that can be retrieved from space. In addition, the aerosol retrieval process itself is hampered by the presence of clouds – particles residing beneath clouds, in the critical cloud droplet formation regions, usually cannot be detected from orbit, and aerosol retrievals in the vicinity of clouds are often complicated by the influence of large relative-humidity gradients and cloud-scattered light. As a result, most space-based studies of indirect effects amount to mining the satellite data for correlations that test theoretical expectations about how aerosols impact clouds.

Figure 13(a)–(c) presents examples of correlations between aerosol amount and cloud droplet size, in two situations where there are both perturbed and unperturbed observations of the same environments. All other things being equal, increasing aerosol amount is expected to result in smaller cloud droplets (commonly called the ‘first indirect effect’) and, if the amount of condensed water in the cloud remains constant, higher cloud albedo. Globally, this qualitative relationship is observed in some regions more than others (Figure 13(d)); the most reliable demonstrations

involve liquid water clouds relatively near the surface. Other consequences of aerosol impacts on clouds include longer cloud lifetimes and reduced precipitation, due to smaller cloud droplets that are less likely to grow to raindrop size, although these have been more difficult to demonstrate, let alone quantify, with satellite remote sensing.

However, space-based measurements have observed cloud ‘invigoration’ (Figure 13(e)). Here, higher concentrations of CCN reduce the size of cloud droplets, inhibiting droplet coalescence until the droplets pass the freezing level. The resulting extra release of energy invigorates the cloud, increasing the cloud fraction and enhancing precipitation. Other recent work has demonstrated a relationship between aerosol concentration and open versus closed convective cell formation, and has shown a correlation between AOD and lightning occurrence as observed from space.

Air quality is monitored primarily with surface-based sampling instruments that directly observe the near-surface particle concentration and can obtain detailed information about particle size distribution and chemical composition. But as it is feasible to cover only a minuscule fraction of the planet with surface samplers, satellite observations can again play a significant role, simply by providing frequent maps of AOD during acute air pollution events. They are also beginning to contribute to longer-term exposure studies, especially when

Figure 13 Indirect effects of aerosols on clouds. (a) Ship tracks off the coast of California, as viewed by AVHRR. combined with chemical transport model results that provide particle vertical distribution and chemical speciation that are otherwise lacking observationally (Figure 14).

Conclusions

Because aerosol amount and type vary on such a wide range of spatial and temporal scales, and exhibit such a diversity of environmental impacts, satellite remote sensing makes an essential contribution to the study of airborne particles. Since the very first orbiting imagers began observing Earth, the scope of satellite data products has provided inspiration, qualitative

indications, and, increasingly, quantitative constraints on the regional and global influences that aerosols exert. Major advances in this field have taken place in the last decade since the previous edition of the *Encyclopedia of Atmospheric Science* was published. New satellite-derived aerosol offerings include monthly global AOD climatologies and time series, near-source and downwind aerosol vertical distribution measurements, regional aerosol type discrimination, aerosol source strengths, and correlative analyses showing the indirect effects of aerosols on clouds. Much of this advancement has come from the current generation of satellite instruments, increasingly sophisticated aerosol field measurement campaigns, and ground-based instrument networks, and from combining

Figure 14 Six-year (2001–06), global-average, near-surface concentration of particles smaller than $2.5\ \mu\text{m}$ in diameter ($\text{PM}_{2.5}$) over land, derived from MISR plus MODIS total-column AOD, combined with vertical distribution from the GEOS-Chem chemical transport model. The vertical distributions were validated using CALIPSO profiles, and derived $\text{PM}_{2.5}$ can be compared with surface station values, which are shown using the same color scale, superposed where available within black circles in this figure. Reproduced from Van Donkelaar, A., Martin, R.V., Brauer, M., Kahn, R., Levy, R., Verduzco, C., Villeneuve, P.J., 2010. data from multiple sources with models. Further advances can be expected as retrieval algorithms continue to be refined, as data and models are analyzed and combined in new and innovative ways, and, eventually, as next-generation space-based aerosol remote-sensing instruments are deployed.

Synopsis

This article discusses the Earth's radiation budget and its role within the climate system. A brief summary of how Earth's radiation budget is determined from satellite observations is provided and the geographical, diurnal, and seasonal variations in its components are shown. The relationship between interannual variations in Earth's radiation budget and their relationship to natural fluctuations in the climate system such as the El Niño-Southern Oscillation are explored, as are the regional patterns of change during the past 12 years. This article also discusses the important role of clouds in modulating Earth's radiation budget at the top-of-atmosphere, surface, and within the atmosphere.

Introduction

The Earth's average temperature is relatively constant from year to year because the Earth emits as much energy to space as it absorbs from the Sun. Without this balance, the Earth would heat up or cool down. Energy from the Sun arrives at the Earth as electromagnetic waves of light that carry radiant energy, or radiation, which can be reflected, absorbed, or transmitted upon entering the Earth-atmosphere system. Most of the radiant energy from the Sun reaches Earth at visible wavelengths (primarily 0.3–2.5 μm), whereas radiation emitted by Earth occurs at wavelengths in the infrared region (primarily 3.5–100 μm). Earth's energy balance is influenced by the composition of the atmosphere, clouds, aerosols, and surface type. A steady increase in the concentration of atmospheric carbon dioxide, methane, and other trace gases since the beginning of the Industrial Revolution is causing an imbalance in the Earth's energy budget. In turn, the Earth has warmed by approximately 0.8 $^{\circ}\text{C}$ during the period 1901–2010. Far less certain are how clouds, aerosols, and the Earth's surface have changed, and how these changes have influenced the Earth's energy balance.

The regional pattern of net radiation (absorbed solar minus emitted thermal radiation) drives the atmospheric and oceanic circulations. The tropics absorb more radiation from the Sun than they emit, while the opposite is true at the poles. To make up for this latitudinal imbalance, the atmosphere and ocean transport energy from the Equator to the poles. The global average radiative imbalance between the surface and atmosphere determines how much energy is available to drive the hydrological cycle and the exchange of sensible and latent heat between the surface and atmosphere. Understanding the vertical and spatial distribution of radiation and how it changes with time is thus critical for understanding climate.

Satellite Observations

There are two major types of radiometers for measuring the reflected solar and emitted thermal radiation from Earth. Wide field-of-view nonscanning radiometers observe from horizon to horizon using either a spherical or flat-plate-type radiometer. Scanning radiometers measure radiation within a relatively

narrow field of view and provide regional coverage of Earth by scanning across the Earth from limb to limb. Scanners provide far better spatial resolution than nonscanners, but they require more complex algorithms to convert the measured radiances to radiative fluxes.

The first attempts at observing Earth's radiation budget from satellites are from the late 1950s, during the early days of the satellite era. The Explorer 7 satellite provided the first usable nonscanning wide field-of-view measurements of the total (reflected solar and emitted thermal) radiation from Earth. The 1960s was a period of rapid advances with the Television Infrared Observational Satellite series, which brought together broadband Earth Radiation Budget (ERB) instruments and five-channel scanning radiometers on the same platform for the first time. Unfortunately, the early satellite missions had lifetimes limited to roughly 1 year or less. It was not until the Nimbus-7 ERB mission in the late 1970s that an extended multiyear ERB data set was collected. ERB observed total solar irradiance and reflected solar and emitted thermal measurements with both scanner and nonscanner instruments. Another satellite mission that provided an extended record is the Earth Radiation Budget Experiment (ERBE), which consisted of scanning and nonscanning radiometers, as well as solar radiometers. The ERBE nonscanner wide field-of-view instrument on the Earth Radiation Budget Satellite (ERBS) was operational from 1985 to 2000. During the 1990s, there were two launches of the Scanner Radiation Budget (ScaRaB) instrument onboard the Meteor and Resurs satellites, which lasted less than 1 year due to the spacecraft anomalies.

Currently, there are three satellites providing global ERB observations. Clouds and the Earth's Radiant Energy System (CERES) scanner instruments are flying aboard the Terra (December 1999–present), Aqua (May 2002–present), and Suomi-NPP (October 2011–present) satellites. Each of the CERES instruments is flying with a multichannel imager, which provides higher spatial resolution data for determining coincident cloud and aerosol property information along with CERES top-of-atmosphere (TOA) radiation. This combination of instruments enables radiative fluxes at the surface and within the atmosphere to be determined at global scales. The CERES processing also utilizes narrowband visible and infrared measurements aboard geostationary satellites to provide additional information about the diurnal cycle of clouds and

radiation between 60° S and 60° N. Since the latter are intended for weather applications, they must be routinely calibrated against higher quality imager and CERES data in order to minimize the impact of instrumental artifacts on the radiation budget record.

Until the early 2000s, ERB missions were limited to either precessing or Sun-synchronous satellite orbits. This changed when Geostationary Earth Radiation Budget (GERB) instruments were launched aboard the Meteosat-8, Meteosat-9, and Meteosat-10 satellites. GERB provides reflected solar and emitted thermal radiation every 15 min over the Meteosat domain (60° S– 60° N and 60° W– 60° E). Additionally, another copy of ScaRaB was launched in October 2011 onboard Megha-Tropiques in a precessing orbit covering the tropics only. The combination of CERES, GERB, and ScaRaB flying concurrently provides unprecedented opportunities for intercalibration and improved diurnal sampling of the Earth's radiation budget.

Figure 1 shows a continuous 31-year record of tropical (20° S– 20° N) TOA broadband outgoing longwave (LW) radiation between 1979 and 2010 from nonscanner and scanner instruments. Figure 1(a) shows rather marked jumps of up to 3 W m^{-2} among the different satellites owing to

absolute calibration differences, which are within measurement uncertainty. Because there is overlap, the entire record can be placed on a common radiometric scale (Figure 1(b)). Increases in tropical mean radiation of up to 5 W m^{-2} are observed during major El Niño–Southern Oscillation (ENSO) events such as the 1997–98 El Niño. The record also provides quantitative data on the LW effect of the Mount Pinatubo eruption and subsequent recovery.

Global Energy Budget

A schematic representation of the Earth's energy budget is depicted in Figure 2. On average, 340 W m^{-2} of solar energy (or, equivalently, about three-and-one-half 100 W light bulbs every 1 m^{-2} over the surface of the Earth) reach the top of the atmosphere. Approximately one-third is reflected to space by clouds, aerosols, air molecules, and the Earth's surface. The Earth–atmosphere system loses approximately 240 W m^{-2} of infrared radiant energy to space. Owing to increased concentrations of CO_2 and other greenhouse gases, Earth is absorbing 0.5 W m^{-2} more radiation than it is emitting to space.

Figure 1 LW TOA flux anomalies for 20° S– 20° N from November 1978 to February 2010 (a) with no overlap correction, and (b) with overlap correction based upon an ERBS Nonscanner (WFOV Edition3_Rev1; red solid line), a Nimbus-7 Nonscanner (green dashed line), an ERBS Scanner (blue solid line), a CERES Terra cross-track (SSF1deg-lite_Ed2.5; blue dashed line), a CERES/TRMM Scanner (Edition2; blue circle), a ScaRaB/Meteor Scanner (green triangle), and a ScaRaB/Resurs Scanner (green circle). Anomalies are defined with respect to the 1985–89 period.

Figure 2 Earth's energy budget.

Approximately 90% of the excess energy from increased concentrations of greenhouse gases is stored in the ocean, and the remainder heats the atmosphere and land, melting snow, and ice. The planetary imbalance and its time variation are determined from a combination of *in situ* ocean temperature measurements to depths of 2000 m and satellite observations of the radiation budget.

The atmosphere absorbs 77 W m^{-2} of the Sun's energy, and 163 W m^{-2} is absorbed at the surface. The latter is used to evaporate water and heat the lower atmosphere. Most of the 240 W m^{-2} in infrared radiation emitted to space at the TOA comes from emission by air molecules and clouds, and a smaller amount ($\sim 40 \text{ W m}^{-2}$) is emitted from the surface and transmitted to space in the atmospheric 'window' wavelength regions. Note that a much larger amount of infrared radiation (398 W m^{-2}) is emitted upward from the surface. The reason why so little of the surface infrared radiation gets through the atmosphere is because atmospheric gases (mainly water vapor and carbon dioxide) and clouds absorb and then reemit 344 W m^{-2} back down to the surface. This process, known as the atmospheric greenhouse effect, is the reason why the average observed temperature at the Earth's surface is 15°C instead of -18°C , the surface temperature in the absence of a greenhouse effect. Summing the reflected solar and emitted thermal radiation terms (net radiation) reveals that there is a surplus of 109 W m^{-2} of radiant energy at the Earth's surface and a deficit of the same amount in the atmosphere. In order to compensate for this radiant energy imbalance, there is

a transfer of 88 W m^{-2} of latent and 21 W m^{-2} of sensible heat from the surface to the atmosphere.

Geographical Variations

The geographic distribution of annual average radiation at the TOA (**Figure 3**) exhibits marked variability, particularly as a function of latitude. Absorbed solar radiation (**Figure 3(a)**) reaches 360 W m^{-2} near the Equator and decreases to 50 W m^{-2} at the poles. The latitudinal difference is a consequence of Earth's geometry: the annually averaged incoming solar radiation per unit area of the Earth's surface is much greater at the Equator than at the poles. The emitted thermal radiation (**Figure 3(b)**) also declines markedly between the Equator and the poles, but the magnitude is half as large, ranging from 290 W m^{-2} at the Equator to 140 W m^{-2} at the poles. In both the absorbed solar and emitted thermal radiation patterns, the Intertropical Convergence Zone (ITCZ) is apparent as a narrow discontinuous band of convective storms resulting in reduced absorbed solar radiation and outgoing thermal radiation. Convective regions are also apparent in **Figure 3(b)** over central Africa, over the Indian Ocean and western tropical Pacific Ocean, and over the Amazon region of South America. In addition to emitting the least amount of radiation, the poles exhibit the greatest hemispheric contrast, with Antarctica emitting up to 50 W m^{-2} less infrared radiation than the Arctic at some latitudes. The net radiation at the TOA (**Figure 3(c)**) also

Figure 3 Geographic distribution of annual average TOA (a) absorbed solar, (b) emitted LW, and (c) net radiation for 2010 (positive downward).

exhibits marked variability with latitude, ranging from a maximum of 105 W m^{-2} in the tropics to a minimum of -130 W m^{-2} over Antarctica. The maximum net radiation into the Earth-atmosphere system occurs at the Equator over the east Indian Ocean. Net radiation is lower in the eastern Pacific Ocean and the Atlantic Ocean in the subtropics due to persistent low clouds that are effective at both reflecting solar radiation and emitting infrared radiation.

The TOA radiation averaged around latitude zones (Figure 4) shows that latitudes within 36° of the Equator gain more radiant energy than they lose through emission, while the opposite is true at higher latitudes. This imbalance drives the general circulation in the atmosphere and ocean, which transports warm air and water in the tropics poleward in order to compensate for the latitudinal net radiation imbalance. In the tropical atmosphere, a mean overturning circulation in the meridional plane, known as the Hadley circulation, is set up with ascending air near the Equator, poleward flow aloft, subsidence in the subtropical regions, and a return flow equatorward near the surface. The Hadley circulation weakens in the midlatitudes, where extratropical cyclones (i.e., weather)

provide the necessary transport of energy to the poles. In the ocean, both wind-driven surface and deep ocean circulations play an important role in meridional ocean heat transport, but the ocean contributes a much smaller portion of the required poleward transport compared to the atmosphere.

Diurnal Variations

The shape of the diurnal cycle of absorbed solar radiation at the TOA depends primarily upon solar insolation (which, in turn, depends upon latitude and season), the diurnal cycle of clouds, and surface albedo. For emitted thermal radiation, the diurnal cycle is strongly influenced by surface temperature, atmospheric profiles of temperature and humidity, and clouds. To illustrate how the diurnal cycle varies in different regions, Figure 5 shows diurnal cycles of absorbed solar, emitted thermal, and net radiation over a Saharan desert region in Algeria, over marine stratocumulus clouds off the west coast of Namibia, and over a land convection over Zambia for January 2005. The diurnal cycle in absorbed solar and net radiation

Figure 4 Zonal annual average of TOA radiation against sine of latitude for year 2010. Separate averages are provided for absorbed solar, emitted longwave, and net radiation (positive downward).

Figure 5 Monthly mean diurnal cycles of absorbed solar, emitted thermal, and net radiation for (a) the Saharan desert (25° N– 26° N, 25° E– 26° E), (b) a marine stratocumulus region (10° S– 11° S, 10° E– 11° E), and (c) land convection (0° S– 1° S, 35° E– 36° E) for January 2005.

exhibits a half-sine shape, peaking around noon, with up to 1000 W m^{-2} of solar radiation absorbed by Earth. The amplitude in absorbed solar radiation for the desert region is smaller than the other two regions because it receives less solar radiation in January due to its more northern latitude and because it has a higher surface albedo than the other regions when the incoming solar radiation reaches a maximum around noon. The peak in emitted thermal radiation over the desert region occurs at 1300 GMT and is fairly symmetric. The diurnal range during this month over the desert region is 36 W m^{-2} . In contrast, emitted thermal radiation over the marine stratocumulus region is only approximately 9 W m^{-2} because the temperature of the low clouds is similar to that of the ocean surface, resulting in little sensitivity in TOA emitted thermal radiation to changes in cloud cover. Over the land convection region, there is a marked asymmetry in the shape of the diurnal cycle, with a maximum emitted thermal radiation occurring in the morning around 1000 GMT, followed by a rapid decrease as convection builds in response to surface warming.

Seasonal Variations

The Earth moves around the Sun in an elliptical orbit with a 3.3% difference in distance between the time when the Earth is closest to the Sun (perihelion; 3 January) and when it is furthest from the Sun (aphelion; 4 July). This results in 7% more solar radiation reaching Earth in January than in July, as illustrated in Figure 6. Also shown in Figure 6 is the seasonal cycle in global mean albedo, defined as the ratio of reflected-to-incident solar radiation. Since clouds are highly reflective (with albedos typically ranging from 0.4 to 0.8) and cover approximately 65% of the Earth, they have a dominant effect on planetary albedo, reflecting approximately 20% of the solar energy reaching the planet, compared to 6% reflected from

molecules and aerosols, and 4% from the surface. Global albedo has a maximum in December, a minimum in August, and weaker secondary minima and maxima in April and May, respectively.

The seasonal cycles in absorbed solar, emitted thermal, and net radiation are shown in Figure 7. The variation in absorbed solar radiation is controlled by solar insolation and Earth's seasonal cycle in albedo, while net radiation variability also depends upon emitted thermal radiation. The Earth absorbs more solar radiation than it emits to space between October and April, when it is closer to the Sun, and emits more than it absorbs between May and September, when it is further away from the Sun. The minimum in net radiation is -10 W m^{-2} in June, 1 month prior to the minimum in solar insolation in July, and the maximum is 8 W m^{-2} in February, 1 month after the maximum in solar insolation in January. The 1-month offset from the minimum and maximum in solar insolation is due to the global albedo seasonal cycle. Remarkably, despite the large 18 W m^{-2} seasonal range in net radiation, the annual average net radiation is only approximately 0.5 W m^{-2} (Figure 2). While the mean TOA solar insolation for January–March exceeds that in October–December by 1 W m^{-2} , the absorbed solar and net radiation are 3 W m^{-2} larger during January–March. The reason is because the global mean albedo for January–March is 0.007 lower than in October–December (Figure 6).

The seasonal cycle range in global mean emitted thermal radiation is 8 W m^{-2} . The Earth emits a maximum of 244 W m^{-2} to space in August, and a minimum of 236 W m^{-2} during December. The annual cycle of emitted thermal radiation is small over the global ocean (less than 2 W m^{-2}), so variations over land are the dominant contributor to the shape of the seasonal cycle in the global mean. The maximum occurs in the Northern Hemisphere summer because the Sun is more intense during that season (due to Earth's tilt about its orbital

Figure 6 Seasonal cycle in TOA global albedo and solar insolation for 2010.

Figure 7 Annual cycle in global absorbed solar, emitted thermal, and net radiation for 2010.

plane) and most of the Earth's land mass resides in the Northern Hemisphere.

Interannual Variations and Trends

Pronounced variations in the seasonal cycle mask smaller but climatologically important year-to-year variations. Interannual anomalies are determined by subtracting the climatological monthly mean of a given month (determined from all years in the time series) from the monthly mean of each individual year for the same calendar month. **Figure 8(a)–8(c)** shows global interannual anomalies in absorbed solar, emitted thermal, and net radiation from March 2000 to June 2012 from CERES. The monthly anomalies (thin line) exhibit variability of approximately 0.5 W m^{-2} (one-standard deviation), largely due to natural variability in the climate system (ENSO, the Northern Atlantic Oscillation, weather systems, etc.). This natural variability masks any systematic trends in the data, for example those due to climate system responses to anthropogenic forcing. For these more subtle changes to be observed, a much longer observation time is needed.

During the positive phase of ENSO (El Niño), the climate system generally releases radiative energy (negative anomalies in net radiation), while the opposite is true during the negative ENSO phases (La Niña). The most prolonged ENSO event in **Figure 8** was the 2008–09 La Niña event. This period was characterized by 22 consecutive months of reduced emitted thermal radiation in the tropics (between June 2007 and March 2009), and positive anomalies in absorbed solar radiation anomalies in both the tropics and globally during much of 2008 and early 2009. The peak net incoming TOA flux anomaly occurred in June 2009, shortly after the transition from La Niña to El Niño conditions, reaching 2.5 W m^{-2} in the tropics and 1.5 W m^{-2} globally. Tropospheric air and sea surface

temperatures are generally cooler during La Niña events, even though the climate system is taking up energy. This excess energy is stored temporarily in subsurface waters at depths between 0 and 300 m, and it resurfaces during El Niño events, where it interacts with the atmosphere.

Regional patterns of change in TOA radiation between March 2000 and June 2012 (**Figure 9(a)–9(c)**) are most pronounced in the equatorial Pacific Ocean and in the Arctic Ocean. Because the record is dominated mainly by weak El Niño events prior to 2007 and much stronger La Niña events after 2007 (**Figure 9(d)**), regional trends in the tropical western Pacific Ocean show negative anomalies in absorbed solar radiation, because convection shifts more westward during La Niña events. Similarly, more solar radiation is absorbed over the central Pacific Ocean with time due to reduced cloud cover, which also results in more thermal emission of infrared radiation. The two effects largely cancel in net radiation (**Figure 9(c)**), however.

Over the Arctic Ocean, **Figure 9(a)** shows large increases in absorbed solar radiation, exceeding 10 W m^{-2} over a large area to the north of North America. While there is also an increase in emitted thermal radiation to space, the net radiation change remains positive over most of the Arctic. These changes accompany a steady decline in Arctic sea ice extent over the past several decades: satellite observations of the monthly average sea ice extent in September show a decline of 13% per decade. The process is self-perpetuating. Because of the large area of open water in late summer, the ice during the following spring tends to be thinner and therefore more vulnerable to melting, leading to further reductions in the sea ice extent. Depending upon their physical and optical properties, clouds can strongly modulate the melting by reflecting much of the solar radiation that would otherwise be absorbed at the surface, and by absorbing and reemitting surface infrared radiation (i.e., the greenhouse effect).

Figure 8 Global anomalies in all-sky TOA (a) absorbed solar, (b) emitted thermal, and (c) net radiation from March 2000 through June 2012. Thin lines correspond to monthly anomalies; solid line is a 12-month running mean through monthly anomalies.

Figure 9 Regional trends in anomalies in all-sky TOA (a) absorbed solar, (b) emitted thermal, and (c) net radiation from March 2000 through June 2012. (d) Multivariate ENSO index.

Impact of Clouds on Earth's Radiation Budget at the TOA, at the Surface, and within the Atmosphere

Clouds have an important role in modulating the TOA, within-atmosphere, and surface radiation budgets at both visible and terrestrial infrared wavelengths. They reduce the amount of solar radiation absorbed by the climate system by increasing the Earth's albedo, and they decrease the loss of terrestrial infrared radiation to space through their greenhouse effect. A common approach for quantifying the influence of clouds on Earth's radiation balance is to compute the difference between the reflected solar and/or emitted thermal radiation observed under all-sky and cloud-free conditions. This difference, called cloud radiative effect (CRE), depends upon the physical and optical properties of clouds, such as their fractional coverage, optical thickness, height, and microphysical properties.

Figure 10(a)–10(c) shows the net CRE at the TOA, within the atmosphere, and at the surface. In regions where the net CRE is negative (positive), clouds have a cooling (warming) effect. At the TOA, extensive areas of net radiative cooling by clouds is observed over the subtropical eastern Pacific Ocean

off the coasts of California and Peru, over the subtropical Atlantic Ocean off the coast of Angola, over the midlatitude southern oceans between 40° S and 60° S, and over the northern Pacific and Atlantic Oceans' storm regions. Compared to cloud-free conditions, clouds in these regions are more effective at reducing how much solar radiation is absorbed by the system than they are at trapping infrared radiation through their greenhouse effect (Figure 10(a)). At the surface, their net radiative impact is much smaller due to a near cancelation of their influence on reflected solar and downward emitted thermal radiation (Figure 10(c)). This is because the base of these clouds is relatively close to the Earth's surface. The within-atmosphere CRE, given by the difference between the TOA and surface CREs, is generally negative for these clouds. This is particularly true for the stratocumulus clouds over the subtropical eastern Pacific and Atlantic Oceans, which typically reside within 2 km of the ocean surface.

A marked negative net CRE is observed at the surface in areas of convective systems, such as over the eastern Indian Ocean and the western tropical Pacific Ocean, along the Equator in the ITCZ, and in land areas over the Amazon and south central

Figure 10 Net cloud radiative effect (a) at TOA, (b) within atmosphere, and (c) at surface for 2010.

Africa. These regions are largely characterized by a combination of relatively narrow vertically extensive convective cores that extend from the surface to the stratosphere, and horizontally extensive but thinner anvil and cirrus clouds, which reside in the upper troposphere at temperatures well below freezing. The latter reduce the amount of solar radiation reaching the surface but have little impact on the downwelling thermal radiation at the surface because of their cold temperatures. As a consequence, the net CRE at the surface is negative (cooling). In contrast, there is a near cancelation between reflected solar and emitted thermal effects at the TOA, as is clearly seen in **Figure 10(a)**. As a consequence, the net CRE within the atmosphere is strongly positive in the convective regions.

Polar regions show a strong positive net CRE at the surface. Since low-altitude polar clouds have similar reflectance to bright snow and ice surfaces, infrared CRE dominates the polar regions, resulting in strong warming at the surface (**Figure 10(c)**) and strong cooling in the atmosphere (**Figure 10(b)**).

Table 1 shows the global average CRE for reflected solar, emitted thermal, and net radiation. On average, the net radiative effect of clouds is that of cooling by 21 W m^{-2} compared to cloud-free conditions, at both the TOA and surface. Approximately 47 W m^{-2} more solar radiation is reflected at TOA compared to a cloud-free Earth due to the presence of clouds, and there is 51 W m^{-2} less solar radiation transmitted to the surface. Clouds reduce the outgoing thermal radiation at the TOA compared to clear conditions by 26 W m^{-2} , and they contribute approximately 30 W m^{-2} more downwelling thermal radiation at the surface. Remarkably, the solar wave and LW effects of clouds cancel within the atmosphere, despite the rather marked geographical differences (**Figure 10(b)**). It is also worth noting that there is a strong vertical gradient in the radiative cooling and heating effects of clouds: they radiatively cool at lower altitudes and warm at the upper troposphere.

The Future of ERB Observations

Because Earth's radiation budget is a fundamental property of the climate system that ultimately determines how energy heats or cools the planet, it is critically important that these measurements continue for many decades to come. Furthermore, climate models project that global temperatures will be $2\text{--}4.5^\circ\text{C}$ warmer than at the beginning of the Industrial Revolution. To place this range into perspective, the average global mean temperature during the last Ice Age was 5°C cooler than present. It is well recognized that cloud changes and their influence on the Earth's radiation budget in a warmer climate comprise the largest source of uncertainty in state-of-the-art climate models. Observations of CREs provide the only meaningful constraints on the climate

model representation of cloud processes. Unfortunately, the record of reliable global observations is still too short to use the observations to discriminate what climate models are placing Earth on the right climate trajectory. The short record is dominated by ENSO and other natural variations in the climate system that enable scientists to test only how well the models represent these short-lived fluctuations.

Extending the ERB record requires a commitment by the international community. Currently, there are plans in the United States to extend the CERES record through the end of the 2010s and into the early 2020s. A CERES instrument will fly on the first Joint Polar Satellite System satellite (JPSS-1) in 2016, and plans are underway to continue the ERB record in the next decade on JPSS-2 in 2021. There are no known plans by other countries to make ERB observations at the time of this writing.

Synopsis

The signals of the Global Positioning System (GPS) encounter refraction in the Earth's atmosphere. In ground-based GPS meteorology, GPS signals are observed at a ground station, and the data can be inverted for precipitable water with accuracy and precision of 2%. In GPS radio occultation (RO), GPS signals are observed in low Earth orbit after traversing the atmosphere, and the data can be inverted for profiles of the microwave refractivity, pressure, and temperature. Between 8 and 30 km, the retrieved refractivity is precise to 0.2%. Both ground-based GPS and GPS RO are ideally suited to climate monitoring and numerical weather prediction.

Introduction

When a microwave signal propagates through the Earth's atmosphere, it is retarded by an index of refraction that is greater than 1; therefore, a signal emitted by a satellite of the Global Positioning System (GPS) is delayed in its arrival at a receiver with respect to its arrival if no atmosphere were present. The index of refraction varies substantially in the atmosphere, with most of the gradient in the vertical direction. Not only is the signal delayed by the atmosphere, but also it is bent in the direction of the gradient to effectively minimize the travel time from the transmitter to the receiver. In GPS meteorology, which is the sounding of the atmosphere for meteorological purposes using the signals of the GPS, the retardation and the refraction of the signal are the two phenomena that enable meteorological sounding of the atmosphere. The two techniques of GPS meteorology are *ground-based GPS meteorology* and *GPS radio occultation (RO)*. Ground-based GPS meteorology is the recording of a GPS signal by a GPS receiver on the Earth's surface. Its primary information is a quantification of the vertically integrated amount of water vapor above the GPS receiver. GPS RO is the recording of a GPS signal by a GPS receiver in a low Earth orbit (LEO). Its primary information is a profile of the microwave index of refraction as a function of height in the atmosphere. Both methods of GPS meteorological sounding have come to play an important role in numerical weather prediction, in atmospheric dynamics, and in climate monitoring. There is little bending present in ground-based GPS meteorology because the GPS signal propagates only a short distance through the atmosphere. Bending of the signal is a pronounced effect in GPS RO because the GPS signal propagates a great distance nearly orthogonally to the gradient of the index of refraction. Processing GPS RO data is consequently a more complex endeavor than processing ground-based GPS data. Both ground-based GPS meteorology and GPS RO are described in this article.

GPS is a constellation of satellites deployed by the US Air Force for the primary function of high-precision positioning. Nominally, there are at least 24 satellites in the GPS system at any given time, but because of continuing replenishment of GPS with new satellites bearing improved technology, there are usually several more than 24 GPS satellites in operation contemporaneously. Each satellite of GPS illuminates the Earth with a set of microwave L-band signals. In GPS

meteorology, the most relevant of the signals is the 'coarse acquisition' (C/A) signal because of its amplitude and because it is modulated by a publicly available pseudorandom code. The C/A signal is broadcast at the L1 frequency, which is 1.57542 GHz. Several other signals are also transmitted, one also at the L1 frequency but encrypted by a secure and publicly unavailable pseudorandom code, and another at the L2 frequency that is secured by the same pseudorandom code. The L1 C/A and the secure L2 signals are tracked in GPS meteorological applications. On average, a GPS receiver on the ground tracks approximately six GPS satellites at any given time.

Other constellations of satellites intended for precise positioning are currently being deployed and should also be useful for meteorological purposes. The European Space Agency is deploying the Galileo system, the Peoples' Republic of China the Compass system, and Russia the GLONASS system. All the positioning systems are referred to collectively as the Global Navigation Satellite Systems (GNSS), and it has become common to refer to the sounding techniques based on GNSS as ground-based GNSS and GNSS RO. At present, GPS remains the only operational GNSS, so only ground-based GPS and GPS RO are discussed here.

Ground-Based GPS Meteorology

In ground-based GPS meteorology, the delay of GPS signals by the atmosphere as received at a ground station is inverted for column-integrated water vapor (IWV), or precipitable water. Because ground-based GPS meteorology is based on timing measurements and is ultimately calibrated using atomic clocks, this technique for measuring precipitable water is widely regarded as the most accurate one and is therefore ideally suited to climate monitoring. It is unfeasible to obtain global coverage of ground-based GPS meteorology because such measurements can be obtained only at fixed stations on the ground where GPS receivers connected to fixed antennas have been placed.

GPS signals traveling through the atmosphere take longer to arrive at a GPS receiver on the ground than if no atmosphere were present. The excess time is multiplied by the speed of light to form the path delay, which has a dimension of distance. The path delay increases with an increasing mass

of air between the transmitting GPS satellite and the receiver, and also increases with increasing water vapor concentration along the path of the ray. When the transmitting GPS satellite is exactly at zenith, or directly overhead, the path delay is simply the integral of the microwave index of refraction n less 1 in altitude:

$$\text{ZPD} = \int_{\text{receiver}}^{\text{transmitter}} (n - 1) dz. \quad [1]$$

Relating the zenith path delay (ZPD) to atmospheric quantities requires an expansion of the microwave index of refraction in terms of state variables of the atmosphere, which is given by:

$$n - 1 = \left(c_1 \rho_d + c_2 \rho_v + c_3 \frac{\rho_v}{T} \right) \times 10^{-6}, \quad [2]$$

in which ρ_d is the density of dry air, ρ_v the density of water vapor, and T the atmospheric temperature. The constants are $c_1 = 222.76 \text{ m}^3 \text{ kg}^{-1}$, $c_2 = 299.0 \text{ m}^3 \text{ kg}^{-1}$, and $c_3 = 1.743 \times 10^6 \text{ K m}^3 \text{ kg}^{-1}$. This expression for the microwave index of refraction is based on a combination of first principles and empirical measurement and is accurate to 0.1%. Vertical integration of the first term in parentheses is proportional to surface pressure because it is a hydrostatic integral. As a result, the ZPD of eqn [1] is separable into a component that is due to surface pressure (the *zenith hydrostatic delay* (ZHD)) and a component that is due to water vapor density (the *zenith wet delay* (ZWD)). The ZHD is the product of $2.2715 \text{ mm hPa}^{-1}$ ($2.2715 \times 10^{-5} \text{ m Pa}^{-1}$) and the surface pressure. This makes the ZWD:

$$\text{ZWD} \approx 10^{-6} \int \left(c_2 \rho_v + \frac{c_3 \rho_v}{T} \right) dz. \quad [3]$$

The ZWD itself is related to the column IWV density. Defining a mean temperature T_m that is the inverse of the water vapor column-weighted inverse temperature,

$$T_m = \frac{\int_{\text{surface}}^{\infty} \rho_v dz}{\int_{\text{surface}}^{\infty} (\rho_v / T) dz}, \quad [4]$$

the column IWV is related to the ZWD by:

$$\text{IWV} = \text{ZWD} \times 10^6 \left(c_2 + \frac{c_3}{T_m} \right)^{-1}. \quad [5]$$

The column IWV is the mass per unit area of water vapor above the ground station. It is related to precipitable water by division of the density of water, 1000 kg m^{-3} . Once the ZPD is determined at a ground station, the ZHD as determined by a measurement of surface pressure is subtracted from the ZPD, and this last equation is applied to the remaining ZWD to retrieve column IWV. The ZHD is $\sim 2.3 \text{ m}$ and can be estimated with the same fractional uncertainty as that of the pressure measurement. The ZWD ranges from 0 to 0.40 m and is known much less precisely than the ZHD. Thus, ground-based GPS meteorology is used to retrieve column IWV. Figure 1 shows a month-long time series of ZWD and column IWV for a GPS ground station.

There are several complicating factors in the retrieval of column IWV by ground-based GPS meteorology. The most dominant one is the specification of the mean temperature T_m . The mean temperature is a function of the vertical distribution of water vapor and temperature and therefore varies in time and space. A single best estimate of the mean temperature is 260 K, but the true value of T_m varies with a standard deviation of 20 K according to location and season, which propagates into a 15% uncertainty in column IWV. However, a measurement of surface air temperature at the location of the GPS receiver reduces the uncertainty in the retrieved column IWV to 2% because the vertical lapse rate of temperature in the troposphere varies little.

Another complicating factor in ground-based GPS meteorology is the mapping of the off-zenith measurement of path delay, or the *slant path delay*, to a ZPD. In the process of ground-based GPS meteorology, the actual measurement is the slant path delay because the transmitting GPS satellite is never exactly overhead. The slant path delay measurements must be mapped to ZPD. The mapping differs from a simple multiplication by cosine zenith angle because the GPS signal does not follow a straight line through the atmosphere when

Figure 1 Zenith wet delay (ZWD) and column-integrated water vapor (IWV) every half hour from the SuomiNet station at Cape Kennedy, Florida, United States, for the month of June 2011.

the GPS satellite is not at zenith. The slant path delay P for a GPS signal is:

$$P = \int_{\text{receiver}}^{\text{transmitter}} nds - L, \quad [6]$$

in which L is the straight-line distance between the transmitting GPS satellite and the ground-based receiver and the integral is along the path of the ray. The strong variation of the index of refraction in altitude causes GPS rays to bend downward as they propagate through the atmosphere, making the path of the integral longer than the straight line connecting the transmitter and the receiver. Hence, the path delay is positive. There is no single expression that can map non-ZPD to ZPD with absolute precision based on the GPS data alone. Mapping functions have been proposed out of necessity, and they take the following form:

$$P = \text{ZHD} \times M_H(\zeta) + \text{ZWD} \times M_W(\zeta). \quad [7]$$

The function $M_H(\zeta)$ maps the ZHD to the slant path delay, and the function $M_W(\zeta)$ maps the ZWD to the slant path delay. Many expressions have been formulated for the two mapping functions, the most complex ones involving many parameters besides the zenith angle ζ and thereby obtaining greater precision. For zenith angles less than $\sim 75^\circ$, the two mapping functions take the same form, and they can map path delay to ZWD with an uncertainty of 0.7 cm (0.007 m). Mapping functions are too imprecise for zenith angles greater than $\sim 75^\circ$, and so ground-based GPS meteorology typically restricts observations to zenith angles less than 75° .

By comparison to other more direct measurements of precipitable water, ground-based GPS measurements of precipitable water are precise to 2 mm (0.002 m) plus 2% of the precipitable water. The measurements are accurate to 2 mm (0.002 m).

Several properties of ground-based GPS meteorology make it an attractive technique for measuring column IWV. First, knowledge of column IWV should constrain the prediction of precipitation in major storms, and so ground-based GPS meteorology is useful in hazard mitigation. Second, it can operate nearly autonomously, yielding estimates of column IWV every 10–30 min. Third, it is mostly insensitive to the presence of clouds, which corrupt the retrieval of column IWV from most remote-sensing data. Fourth, GPS receivers suited to ground-based GPS meteorology are typically inexpensive, their cost being approximately US\$1 million. Finally, because ground-based GPS meteorology is ultimately a timing measurement, which can be calibrated against atomic clocks, it is ideally suited to long-term climate monitoring. Its primary limitation is that it is ground based, meaning that it cannot practically obtain global coverage. Its primary competition for climate monitoring, aside from GPS RO (discussed further in this article), is passive microwave sounding and water vapor radiometry. While passive microwave sounding and radiometry from space do obtain global coverage, their sensitivity to clouds inhibits the precision of the retrieval of column IWV. Furthermore, because passive microwave sounding from space is a measurement of millimeter-wave radiation emitted from the Earth's atmosphere, it is much more difficult to calibrate than GPS

measurements. Water vapor radiometry is difficult to calibrate as well, because it is a broadband measurement.

At present, many networks of ground-based GPS receivers are used to monitor column IWV, and some have been deployed specifically for that purpose. Assimilation of slant path delay into numerical weather prediction generally shows improvement in the forecasting of precipitable water and precipitation out to 12 h in the future but weaker impact further into the future. Results have been less conclusive regarding predictions of precipitation amount, temperature, geopotential height, and winds. As of 2008, the time series of precipitable water measurements have not covered a period long enough to detect anything more than a marginally significant upward trend. Figure 2 is a map of the GPS ground stations of SuomiNet, which is dedicated to monitoring column IWV. It is just one of many such networks worldwide.

GPS RO

Whereas ground-based GPS meteorology is based on the reception of GPS signals with a receiver on the Earth's surface, GPS RO is based on the reception of GPS signals with a receiver in LEO. From the perspective of a LEO satellite with an orbital period of ~ 100 min, each GPS satellite can appear to rise or set on the Earth's horizon several times daily. During these events, the Earth's atmosphere is said to occult the GPS satellite, and data are collected from the time that the GPS ray is 100 km above the Earth's surface until the Earth's surface itself occults the signal. This is a single RO. The signal's phase and amplitude as a function of time are the recorded data. Since the atmosphere has a microwave index of refraction that mostly decreases with height, the transmitted signal is refracted downward as it transects the atmosphere (cf. Figure 3). The bending of the signal increases the optical path delay well beyond what would have been expected if no atmosphere were present. Data on the optical path delay can be transformed to an estimate of the total angle through which the signal is bent, which in turn can be transformed into a profile of the refractive index of the atmosphere. Subsequent information can be incorporated to retrieve profiles of temperature, pressure, and water vapor as functions of geopotential height.

Figure 2 A map of the locations of the ground stations of SuomiNet, used in monitoring column-integrated water vapor in the United States.

Figure 3 Spreading of GPS rays by refraction in the Earth's atmosphere. A spacecraft in LEO (dashed red line) receives the bent GPS signal.

As in ground-based GPS meteorology, GPS RO is a timing measurement that can be absolutely calibrated with an accuracy of <1 part in 10^{15} . It, too, is insensitive to clouds. Because it is space based, the coverage is global but also nonuniform. The speed of a LEO satellite in its orbit and the large number of satellites in the GPS constellation combine to yield many hundreds of RO events daily for a single LEO satellite. GPS RO is at its most precise and accurate in the region spanning approximately 8–30 km in height, commonly referred to as the upper troposphere and lower stratosphere. Below that region, the complexity of signal dynamics in a highly heterogeneous water vapor field prevents regular and precise tracking of the GPS signal. Above that region, the residual ionospheric influence and the weak bending of the GPS signal in the presence of noise degrade the accuracy and precision of the measurement. Because it records the phase of the GPS signal during an occultation event, methods paralleling those of holography can be applied to obtain vertical resolution in the atmosphere that is Fraunhofer limited rather than Fresnel limited. Accounting for smoothing of retrieved quantities, the vertical resolution is approximately 100–200 m.

The briefest description of the relationship between the refractive properties of the atmosphere and the measured phase and amplitude in a GPS RO is Hamiltonian optics, in which the eikonal Φ is the path delay (in radians) as a function of space and time and the Hamiltonian is the angular frequency $H = \omega = |\mathbf{k}|c/n(\mathbf{q})$, where $\mathbf{k}$ is the wavevector, c the speed of light, and $n(\mathbf{q})$ the index of refraction as a function of the coordinates $\mathbf{q}$. Since the Earth is close to spherically symmetrical on scales of tens to hundreds of kilometers in the horizontal, it is appropriate to consider the orbital azimuth θ as a Hamiltonian coordinate (cf. Figure 4 for geometry). The

Figure 4 Geometry of the ray path. The orbital azimuth is θ , the orientation of the ray with respect to the local vertical is ψ , and the radial coordinate is r .

momentum conjugate to the orbital azimuth is $p_\theta = -(\partial\Phi/\partial\theta) = nrk_0 \sin \psi$, in which k_0 is 2π divided by the vacuum wavelength of the GPS carrier and ψ is the angle between the radial and propagation directions. In Hamiltonian systems, the time tendency of momentum is $dp_\theta/dt = -\partial H/\partial\theta$, which becomes:

$$\frac{dp_\theta}{ds} = k_0 \frac{dn}{d\theta}, \quad [8]$$

in which s measures distance along the path of the ray. Consequently, $nr \sin \psi$ is a constant along the path of the ray if the atmosphere is perfectly spherically symmetric meaning n does not depend on θ . The conservation law $nr \sin \psi = a$ is known as Bouguer's law, and, by trigonometry, a is the impact parameter, or the ray's asymptotic miss distance from the center of curvature of the Earth at the transmitter or the receiver (cf. Figure 5 for geometry). The angle through which the ray bends in the course of its propagation, in differential form along the path of the ray, is $d\alpha = d\psi + d\theta$. The application of trigonometry and Bouguer's law gives the following differential form for the bending angle along the path:

$$d\alpha = -\tan \psi \frac{dn}{n} = \pm \frac{a}{\sqrt{n^2 r^2 - a^2}} \frac{dn}{n}. \quad [9]$$

The $\pm$ is positive for downward propagation into the atmosphere and negative for upward propagation out of the atmosphere. Integrating along the path of the ray gives a function defining the bending angle as a function of the impact parameter:

$$\alpha(a) = -2a \int_{r_{\min}}^{\infty} \frac{d \ln n/dr}{\sqrt{n^2 r^2 - a^2}} dr. \quad [10]$$

This is the forward model for the observation given the profile of the index of refraction as a function of radial distance $n(r)$. The profile of the index of refraction is a function of pressure, temperature, and humidity in the atmosphere as prescribed by eqn [2].

In GPS RO, while the fundamental observable is the phase and amplitude of the GPS signal as a function of time, the derived quantity upon which all subsequent processing is based is the bending angle as a function of the impact parameter $\alpha(a)$. An Abelian integral transform of the forward model for the bending angle is applied to retrieve the profile of the index of refraction as a function of the impact parameter:

$$\ln n(a) = -\frac{1}{\pi} \int_a^{\infty} \frac{\alpha(a')}{\sqrt{a'^2 - a^2}} da'. \quad [11]$$

The dependence of the retrieved index of refraction on the impact parameter of the ray is converted to dependence on radial distance by determining the value of the radial distance at the ray's minimum radius, which is the largest r that satisfies $n(r) \cdot r = a$. Spherical symmetry is assumed, leading to Bouguer's law and the above derivation.

For the Earth's atmosphere, the refractivity, or $N = (n - 1) \times 10^6$, is roughly 330 at the Earth's surface. In the tropics, it can be as large as 400. While the 'wet' terms (c_2 and c_3 terms of eqn [2]) exceed 30% of the dry term (c_1 term of eqn [2]) only in the tropics, in the lower

Figure 5 Geometry of a GPS radio occultation. See the text for the description of the quantities. The impact parameter a and the radial distances R_{GPS} and R_{LEO} to the GPS and LEO satellites, respectively, refer to the local center of curvature of the Earth's surface nearest the closest approach of the ray, which strays from the Earth's center by a few tens of kilometers.

atmosphere the wet terms combined are far more variable than the dry term. The typical bending angle at the Earth's surface is 1° , but it becomes much larger in the presence of critical refraction and near-critical refraction (discussed further in this article).

RO: Geometric Optics

The bending angle as a function of impact parameter can be derived from the observation of the phase of the GPS signal during a RO event and subsequently transformed to a profile of the index of refraction. The difference between the rate of change of the signal's optical path and the rate of change of the distance between the GPS and LEO satellites is known as the excess phase rate and is easily determined by the measurement of phase and the satellites' positions. The excess phase rate is nonzero only if the ray is refracted, causing retardation and bending of the signal. The excess phase rate $\dot{L}$ is related to the GPS satellite's and the LEO satellite's velocities by:

$$\dot{L} = \mathbf{v}_{\text{LEO}} \cdot (\mathbf{s}_{\text{LEO}} - \mathbf{s}) - \mathbf{v}_{\text{GPS}} \cdot (\mathbf{s}_{\text{GPS}} - \mathbf{s}), \quad [12]$$

in which $\mathbf{v}_{\text{LEO}}$ and $\mathbf{v}_{\text{GPS}}$ are the velocities of the LEO and GPS satellites, $\mathbf{s}_{\text{LEO}}$ and $\mathbf{s}_{\text{GPS}}$ are unit vectors in the direction of the ray path at reception by the LEO satellite and at transmission by the GPS satellite, and $\mathbf{s}$ is the unit vector pointing directly from the GPS to the LEO satellite. An assumption of spherical symmetry, which guarantees that the impact parameter for the ray is the same on the GPS and LEO sides of the ray's path, permits the determination of the bending angle $\alpha = \cos^{-1}(\mathbf{s}_{\text{LEO}} \cdot \mathbf{s}_{\text{GPS}})$ and the impact parameter $a = |\mathbf{s}_{\text{LEO}} \times \mathbf{R}_{\text{LEO}}|$, in which $\mathbf{R}_{\text{LEO}}$ is the coordinate vector of the LEO satellite with respect to the occultation's center of curvature.

In eqns [10]–[12], a few approximations have been made for the sake of presentation. First, the GPS and LEO satellites are assumed to travel through a vacuum in which the index of refraction is exactly 1. Second, relativistic effects are assumed to be small and hence are neglected. The former is assumed in all processing of GPS RO to date. The latter is not assumed: relativistic effects are fully accounted for in the processing of GPS RO.

RO: Physical Optics

Several complications arise in the application of the integral transform of eqn [11] for retrieving profiles of the index of refraction. Aside from spherical asymmetry of the index of refraction, the three most significant complications are atmospheric multipath, diffraction, and critical refraction. Atmospheric multipath occurs when more than one ray connects the occulted GPS satellite and the LEO satellite. It typically occurs in the lower troposphere, particularly in the tropics, when layers of very humid air overlie layers of much drier air. Each ray is associated with a different phase delay rate, and the observed signal experiences a beating phenomenon because of the rays' interference with each other. Diffraction arises when geometric optics – as presented in the equations in this article – loses its validity. Geometric optics is valid as long as the refracting medium has no significant structure on scales smaller than the Fresnel scale, which, for RO, is ~ 1 km (~ 1000 m). When a pronounced structure on smaller scales is encountered, such as the tropopause or the top of the planetary boundary layer, high-frequency ringing of the excess phase delay measurement and its amplitude result. Critical refraction, sometimes called 'superrefraction,' occurs in those layers for which the product $n(r) \cdot r$ is greater than $n(r) \cdot r$ at a level higher in the atmosphere. The index of refraction in a critical layer is indeterminate because no ray ever reaches its minimum in a critical layer, and the index of refraction beneath it is always underestimated. Critical layers are most often associated with maritime subsidence and marine stratocumulus.

The effects of diffraction and multipath can be corrected using a variety of techniques that have been implemented, which are commonly referred to as physical optics. These techniques are based on the same principle that makes holography possible. Whereas most remote-sensing techniques measure the amplitude or intensity of radiation from an incoherent source, RO tracks the phase of a refracted signal. The phase information can be used to reconstruct the electric field anywhere in postprocessing. Four methods of physical optics processing presented to date are canonical transform (types 1 and 2), full-spectrum inversion, and phase matching. All are conditioned on the WKBJ approximation, which requires that nonwave structures of the field occur on scales much larger

than the wavelength of the carrier signal. Both types of canonical transform consider field position and wavevector as coordinate-momentum pairs of a Hamiltonian system and transform to the impact parameter and bending angle, another Hamiltonian coordinate-momentum pair, by canonical transform. Full-spectrum inversion associates specific frequencies of a Fourier transform of the complete RO signal with individual rays, even if multiple rays are present at a given instant. Phase matching is a variation of full-spectrum inversion that accounts for noncircular orbits. All are rooted in the theory of Fourier integral operators.

There is no known method to recover the index of refraction in and below critical refraction layers accurately with RO data alone. In addition, there is no agreed upon method to retrieve atmospheric properties accurately in the presence of spherical asymmetry. In the case of the latter, the impact parameter is not the same on the GPS and LEO sides of the occultation, and $nr \sin \psi$ is not constant along the ray.

RO: Signal Amplitude

In the geometric optics approximation, the amplitude of the received signal is strongly related to the geometry of the occultation event and the bending-angle profile dictated by the atmosphere according to eqn [10]. It is derived by conserving radiant flux from transmission from the GPS satellite to reception by the LEO satellite (cf. Figure 5 for the geometry and angles). The radiant flux dF emitted from the GPS satellite inside a tube surrounding the ray is:

$$dF = I_{\text{GPS}} \cdot \sin \beta_{\text{GPS}} d\varphi d\beta_{\text{GPS}}, \quad [13]$$

in which I_{GPS} is the radiant intensity of the emitted GPS radiation. By conserving the radiant flux in the tube to the receiver, it is related to the irradiance E_{LEO} of the signal received at the LEO satellite. At the LEO satellite, the radiant flux dF is:

$$dF = E_{\text{LEO}} \cdot R_{\text{LEO}}^2 \cos \beta_{\text{LEO}} \sin \theta d\varphi d\theta, \quad [14]$$

in which E_{LEO} is the irradiance of the signal at the LEO satellite. The radiant flux dF of eqn [14] is equal to the radiant flux of eqn [13] if the signal is nowhere attenuated along its path. By geometry, $R_{\text{LEO}} \sin \beta_{\text{LEO}} = R_{\text{GPS}} \sin \beta_{\text{GPS}} = a$ and $\beta_{\text{GPS}} + \beta_{\text{LEO}} + \theta - \alpha = \pi$. Differentiation and substitution give the equation for irradiance at the LEO satellite:

$$E_{\text{LEO}} = I_{\text{GPS}} \frac{a}{R_{\text{GPS}} R_{\text{LEO}}} \frac{1}{D_{\text{GPS}} + D_{\text{LEO}}} \frac{1}{|Q| \sin \theta}, \quad [15]$$

in which $D_{\text{GPS}} = (R_{\text{GPS}}^2 - a^2)^{1/2}$ and $D_{\text{LEO}} = (R_{\text{LEO}}^2 - a^2)^{1/2}$ are the distances from the GPS satellite to the Earth's limb and from the LEO satellite to the Earth's limb, respectively. The defocusing factor Q is given in terms of the reduced limb distance $D \equiv (1/D_{\text{GPS}} + 1/D_{\text{LEO}})^{-1}$:

$$Q \equiv 1 - D d\alpha/da. \quad [16]$$

The differential bending angle, $d\alpha/da$, is almost everywhere negative because ray bending increases with depth in the atmosphere, and thus the defocusing factor is almost always greater than 1. For GPS RO, the term that varies the most over the course of a single RO event is the defocusing factor Q . The differential bending is illustrated as the spreading of rays in

Figure 3. The deeper the ray penetrates into the atmosphere, the weaker the signal becomes. The amplitude of the signal is proportional to the square root of the irradiance at the LEO satellite; thus, it is proportional to $Q^{-1/2}$.

The expressions given in this article for the signal amplitude do not strictly apply in the presence of diffraction and atmospheric multipath. In cases of atmospheric multipath, multiple signals connect the occulted GPS satellite and the LEO satellite, and those signals interfere with each other, resulting in a beating pattern in amplitude and phase. When the multiple rays overlap each other, a strong diffraction pattern occurs. In situations like these, the processing of the data is best handled by physical optics, the effect of which is to set the reduced limb distance $D \rightarrow 0$ and hence the defocusing factor $Q \rightarrow 1$. The postprocessed amplitude of the signal does not vary with impact parameter.

The amplitude of the received RO signal is related to the apparent vertical motion of the signal in the atmosphere. From the viewpoint of the LEO satellite, the image of the GPS satellite appears to descend into the Earth's atmosphere as a setting occultation progresses and is described as the time rate of change of the impact parameter, $\dot{a}$. As the ray connecting the GPS and LEO satellites experiences stronger bending, the ray's apparent descent slows. If no ray bending were present, the apparent vertical motion of the ray would be $\dot{a} = -D\dot{\theta}$, in which $\dot{\theta}$ is the rate of angular separation (with respect to the center of curvature) of the GPS and LEO satellites in orbit. In the presence of differential bending, however, conservation of radiant energy leads to the actual apparent vertical motion of the image of the transmitter to be as follows:

$$\dot{a} = -D\dot{\theta}/Q. \quad [17]$$

The reduced limb distance for most RO missions is $D \approx 3000$ km (3×10^6 m). In the absence of defocusing, the maximum descent rate for RO events is 3000 m s^{-1} .

RO: Calibration

While GPS RO is sometimes referred to as 'self-calibrating,' there still is a procedure for assuring the accuracy and precision of the timing measurements that constitute a RO observation. If geometric optics processing is applied, the determination of $\alpha(a)$ depends on highly precise and accurate determination of the vector velocities of the GPS and LEO satellites. If physical optics processing is applied, the integrals to be computed rely upon highly precise determination of the satellites' positions as a function of time. In either case, precise knowledge of the satellites' orbits is obtained by precise orbit determination, a computation in which data collected over ~ 24 h periods by a worldwide network of GPS receivers on the ground are used to determine the orbits of the GPS satellites. Also in precise orbit determination, data collected by the LEO satellite from nonocculted GPS satellites are used to determine the orbit of the LEO satellite.

The measurement of the excess phase rate must be calibrated either by using a suitably stable atomic clock onboard the LEO satellite or by referencing a clock on a nonocculted GPS satellite during each RO event. The latter is accomplished

by measuring the phase of the signal of the nonocculted GPS satellite at the same rate as the excess phase delay of the occulted GPS satellite. This procedure for calibration is called *single differencing*. If the clocks onboard the GPS satellites are not deemed sufficiently stable for calibration of a RO event, the signals of both the occulted GPS and the referenced GPS satellites are observed by a GPS receiver on the ground that is tied to an ultrastable atomic clock. This method of calibration is called *double differencing* (cf. Figure 6). In most applications of GPS RO retrieval, single differencing has been found to be sufficiently precise and accurate, thus eliminating the complication of finding a ground station that tracks both the occulted GPS satellite's signal and the reference GPS satellite's signal during the RO event. In *zero differencing*, the clock onboard the LEO satellite is sufficiently stable by itself that a reference nonocculted GPS satellite need not be observed by the LEO satellite.

Before the ray connecting the occulted GPS satellite to the LEO satellite enters the Earth's atmosphere, it must first propagate through the ionosphere. The Earth's ionosphere is highly dispersive, introducing an inverse square dependence on the frequency of the carrier signal to the expression for the index of refraction. The refraction of rays in the ionosphere lends RO well suited to profiling the density of electrons in the ionosphere, but in the neutral atmosphere it contributes a source of error in the retrieval of temperature, pressure, and humidity. As part of the process of calibrating a RO event, the receiver onboard the LEO satellite tracks two signals of GPS rather than just one. The primary, strongest signal is L1 C/A, with a carrier frequency of 154×10.23 MHz; the secondary signal is the encrypted L2 signal, with a carrier frequency of 120×10.23 MHz. Dispersion in the ionosphere causes each of

the two signals to take a different path through the atmosphere. The standard ionospheric calibration is a linear combination of the bending-angle profiles for L1 and L2 to yield an ionosphere-corrected bending-angle profile $\alpha_{LC}(a)$:

$$\alpha_{LC}(a) = \frac{154^2 \cdot \alpha_{L1}(a) - 120^2 \cdot \alpha_{L2}(a)}{154^2 - 120^2}. \quad [18]$$

While this ionospheric calibration is standard in retrieval algorithms, it is nevertheless difficult to apply because the L2 signal is modulated by a secure encryption. Modern-day RO receivers track L2 using software that correlates it either against an L1 signal that is subject to the same encryption as L2 or by semicodeless tracking. As a result, the L2 signal is much weaker than the L1 C/A signal and is typically tracked to only ~ 10 km altitude. A modernized GPS L2, called L2C, that is modulated by a publicly available code is becoming operational and should alleviate the difficulties of tracking L2 that have been experienced to date.

RO: Retrieval of Atmospheric State Variables

There is no single way to convert profiles of the index of refraction to profiles of temperature, pressure, and humidity. The hydrostatic equation constrains the solution, but there is still one too many unknown variables, a problem that is known as the *wet-dry ambiguity* in GPS RO. Many techniques, almost all of which are a type of variational data assimilation, have been incorporated to resolve the wet-dry ambiguity. Qualitatively, GPS RO can be considered a humidity sounder in the lower troposphere and a temperature sounder above. Prior uncertainty in humidity propagates to a greater (lesser) uncertainty in the index of refraction than does prior uncertainty in temperature in the lower troposphere (upper troposphere and stratosphere).

The most basic retrieval schemes do not attempt a resolution of the wet-dry ambiguity. Instead, they retrieve pressure and temperature as if there were no water vapor present and call those quantities *dry pressure* and *dry temperature*. Dry pressure is always greater than kinetic pressure, and the difference increases the moister the environment becomes. Dry temperature, in contrast, is always less than the kinetic temperature. In climate research, efforts are being made to treat the index of refraction, dry pressure and dry temperature, in addition to bending angle as state variables that can be directly compared to model output of the same quantities.

The next step in sophistication in the retrieval of atmospheric state variables is to assume either temperature or humidity in order to retrieve the other. In this approach, in the upper troposphere and stratosphere, a profile of the water vapor partial pressure is assumed from an analysis of numerical weather prediction (NWP) or climate reanalysis in order to retrieve temperature. Likewise, a profile of temperature is assumed in order to retrieve specific humidity in the lower troposphere. The level of transition is ad hoc. One retrieval system has set the level of transition as the highest tropospheric level at which the temperature is 250 K.

With increasing sophistication, humidity and temperature are retrieved by one-dimensional variational assimilation (1DVAR). Variational assimilation, as an application of Bayes's

Figure 6 Calibration by single differencing requires observation of the 'reference GPS' by the LEO satellite. Calibration by double differencing requires observation of both the 'occulted GPS' and the reference GPS by a ground station such as one tied to the time standard at the US National Institutes of Standards and Technology (NIST) facility in Boulder, Colorado. All GPS satellites are used for precise orbit determination of the LEO satellite.

theorem, blends prior knowledge of temperature and humidity, usually taken from a numerical weather prediction or analysis, with data in a way that optimizes the posterior knowledge of both temperature and humidity. 1DVAR objectively quantifies the more qualitative approach (described in this section) that RO is a humidity sounder in the lower troposphere and a temperature sounder everywhere above. The forms of variational assimilation used in numerical weather prediction (3DVAR, 4DVAR, and the Ensemble Kalman Filter) follow the same principle as 1DVAR. Figure 7 shows a 1DVAR retrieval of one RO profile obtained by the Constellation Observing System for Meteorology, Ionosphere and Climate (COSMIC) project.

At present, the following institutions have published retrievals of RO data:

- The COSMIC Project Office, University Corporation for Atmospheric Research, Boulder, CO, United States (www.cosmic.ucar.edu).
- The NASA Jet Propulsion Laboratory, Pasadena, CA, United States (genesis.jpl.nasa.gov).
- The European Organization for the Exploitation of Meteorological Satellites (EUMETSAT) Radio Occultation Meteorology Spacecraft Application Facility, Copenhagen, Denmark (romsaf.org).
- The Alfred Wegener Centre of the University of Graz, Austria (globclim.org).
- The Geophysical Research Centre, Potsdam, Germany (gfs-potsdam.de).

RO: Spatial Resolution

The vertical resolution of a retrieval of GPS RO depends on the processing method. If geometric optics was used in the estimation of bending angle as a function of impact parameter, then the vertical resolution is determined by the vertical dimension of the

first Fresnel zone. In the absence of bending, the size of the Fresnel zone is $(2\lambda D)^{1/2}$. In the presence of bending, the Fresnel zone is reduced in the vertical direction, thus increasing the vertical resolution. The amount by which it is reduced in the vertical direction can be determined by the amplitude of the signal, which is directly proportional to the area of the Fresnel zone. Since the amplitude of the signal is proportional to the inverse square root of the defocusing factor, the vertical resolution of GPS RO is $(2\lambda D/Q)^{1/2}$. For L1, the wavelength of the carrier signal is 0.19 m, and hence the vertical resolution is $1070 \text{ m} \cdot Q^{-1/2}$. The transverse horizontal resolution is also the Fresnel size, and it is unaffected by differential bending of the ray.

If physical optics is applied in the reconstruction of $\alpha(a)$, the effective reduced limb distance tends to zero and hence so does the Fresnel zone. In fact, Fresnel diffraction is not the limiting factor in the vertical resolution, but Fraunhofer diffraction is. In Fraunhofer diffraction, the angular resolution of the antenna is the wavelength of the signal divided by the horizontal dimension of the antenna. In GPS RO, the antenna is effectively the path traversed by the LEO spacecraft perpendicular to the direction of the ray during which data are recorded. If data are recorded for 60 s for a LEO spacecraft moving 7 km s^{-1} (and $\beta_{\text{LEO}} \approx 65^\circ$), the Fraunhofer-limited resolution is 3.2 m. In practice, though, the vertical resolution is dictated by the limited amount of data collected and the smoothing algorithms applied to reduce noise in the retrieval. For most applications of physical optics processing, the vertical resolution is effectively 100–200 m.

The horizontal resolution of GPS RO can only be arbitrarily defined since it is a limb-sounding technique. If one considers the horizontal path through which an occultation ray experiences 68% of its bending, the horizontal resolution is $2(HR_e)^{1/2} \approx 390 \text{ km}$ ($3.9 \times 10^5 \text{ m}$), in which the scale height H is $\sim 6000 \text{ m}$ and the radius of the Earth R_e is 6378 km ($6.378 \times 10^6 \text{ m}$). Using the scale height is appropriate in the estimation of the horizontal resolution of GPS RO because most of the contribution to the integral of eqn [11] and the

Figure 7 Retrieval of refractivity, temperature, and specific humidity from a radio occultation obtained by the COSMIC project, 23 June 2010, at 19°N , 118°W . The altitude is the geometric distance from a best-fit ellipsoid to the Earth's surface. The retrieval of temperature and specific humidity was obtained by 1DVAR at the COSMIC Project Office. The background profile is taken from operational analyses of the European Centre for Medium-Range Weather Forecasting (ECMWF) (black). The occultation data is blue.

hydrostatic integral are contributed over a scale height in the vertical. If smaller structures in the vertical are of greater interest, then their vertical dimensions are more suitable than the scale height in the estimation of the horizontal resolution of GPS RO.

RO: Sources of Uncertainty

The sources of uncertainty in GPS RO have been documented extensively. They come in two distinct families: one pertaining to the upper stratosphere and the other to the lower troposphere. In the case of the former, the vertical structure of the error has an envelope that is inversely proportional to pressure, and thus error decreases exponentially with depth with an e -folding scale given by the pressure scale height. Chief among those errors are residual uncertainty in ionospheric calibration, and uncertainty in initiating the transform of eqn [11] and in initiating the hydrostatic integral. All told, the uncertainty at 50 km altitude is 3% in refractivity or 300 m in geopotential height after smoothing over 3000 m. Receiver noise contributes a random error of 2% over the same smoothing interval. In the case of the latter, the dominant source of error is spherical asymmetry. Water vapor is highly heterogeneous in the Earth's atmosphere, leading to spherical asymmetry in the index of refraction. The uncertainty is approximately 1% in refractivity and 60 m in geopotential height in the lowest 5 km of the atmosphere.

Almost every source of error is anticipated to be random in nature; thus, averaging many RO soundings together may yield a climatology that is unbiased. In the case of ionospheric residual, a consequence of incomplete ionospheric calibration, a systematic component to the error may exist depending on the phase of the 11-year solar cycle. Comparison of climatological averages constructed by several independent retrieval centers shows that the structural uncertainties induced by initialization of the transform of eqn [11] and the hydrostatic integral dominate.

In summary, GPS RO performs best in the 8–30 km height region, where the refractivity N can be retrieved with a precision of 0.2% and an accuracy that is an order of magnitude better.

RO: Scientific Applications

GPS RO, because of its several unusual properties, has been used for many applications. Foremost among these is numerical weather prediction because of the density and global distribution of RO data, the data's sensitivity to geopotential height, their insensitivity to clouds, and their high precision and absolute calibration. Many of RO's properties make it comparable in information content to radiosondes but with the advantage of dense coverage of the Earth's Southern Hemisphere. In numerical weather prediction, GPS RO has already greatly improved analysis and prediction, especially in the Southern Hemisphere. Improvement in the prediction of precipitation has proven elusive, but that may well be a consequence of inadequate spatial resolution of the forecast model as much as it is a consequence of the long limb-path of the GPS RO signal. GPS RO has also been used in climate studies, revealing a marginally significant climate trend over the record

of GPS RO data. Finally, GPS RO has been used in studies of atmospheric dynamics, directly revealing wave generation by convection, tropopause variability, the atmospheric tides, the atmospheric signal of El Niño and the Southern Oscillation, and stratospheric internal gravity wave activity.

GPS RO Missions

GPS RO commenced in 1995 and continues to the present. Because the equipment for GPS RO sounding is inexpensive, most of the missions have been by opportunity wherein the GPS receivers are secondary instruments on satellites whose prime instruments have been technologically more complex and hence substantially more expensive. The first proof-of-concept GPS RO mission was GPS/Met, a mission of opportunity. Other missions of opportunity since then have been Ørsted, Sunsat, SAC-C, CHAMP, GRACE, TerraSAR-X, TanDEM-X, and Oceansat-2. The operational GPS RO missions have been the six-satellite COSMIC constellation and Metop-A. More missions are planned.

The various missions have achieved varying degrees of performance according to their design and implementation. Individual occultation events can be categorized as 'setting' or 'rising,' depending on whether the occulted GPS satellite appears to be setting into the Earth's limb or rising into it. The former happens in the antiveloc direction of the LEO satellite, and the latter in the forward-velocity direction. Many missions observe only the setting events because they configured only antiveloc-oriented occultation antennas. Also, missions have implemented different algorithms for tracking GPS signals during occultation events, with some performing better than others especially during instances of multipath and diffraction. The need to remove ionospheric influence dictates tracking both the L1 and L2 GPS signals, and L2 is notoriously difficult for civilian GPS receivers to track for the reasons given in this article. Poorer tracking of L2 implies degraded removal of ionospheric influence. The mission that best tracked L2 was the first, GPS/Met, because the US Air Force disabled the secure encryption on L2 for four month-long periods in 1995–97 for the sake of GPS/Met RO. Beginning with Metop-A and Oceansat-2, the antennas used to track RO signals are phased arrays in order to greatly augment the signal-to-noise ratio of RO signals. This is expected to enhance the accuracy and precision of retrieval in the lowest few kilometers of the atmosphere.

Measuring Ozone from Space – TOMS and SBUV

RD McPeters, NASA Goddard Space Flight Center, Greenbelt, MD, USA

© Published by Elsevier Ltd.

Synopsis

Space-based measurements of ozone on a global basis began with the Backscatter Ultraviolet instrument flown on Nimbus 4 in 1970. A series of similar instruments flown by National Aeronautics and Space Administration and the National Oceanic and Atmospheric Administration have documented the development of an ozone hole over the Antarctic each October, and a drop in global ozone beginning in the 1980s. This important program for the monitoring of global ozone levels is expected to show the slow recovery of ozone over the coming decades as a result of international agreements to regulate the release of ozone-depleting chemicals.

Introduction and History

In the beginning, only a few scientists were interested in ozone. Popular interest came later, in the late 1970s, when the possible destruction of the ozone layer by chlorofluorocarbons (CFCs) was realized. The idea that ozone could be measured quantitatively from a satellite was first put forward in 1957 by Singer and Wentworth. In 1967, Dave and Mateer published a theory for the derivation of the total column amount of ozone from a satellite backscatter instrument. This theory was used for the interpretation of the data from the first instrument to measure ozone from space, the Backscatter Ultraviolet instrument, launched on the Nimbus 4 satellite in 1970. It made nearly global measurements for 2 years and then operated more sporadically for an additional 5 years. When Farman's paper on low ozone in the Antarctic was published in 1985, ozone maps from the Total Ozone Mapping Spectrometer (TOMS) revealed that this was a continent-wide phenomenon and not local. This is the power of satellite measurements of ozone.

The modern data record of global ozone measured from space starts with the launch of the Nimbus 7 satellite in 1978. The satellite carried two ozone-measuring instruments, TOMS and the Solar Backscatter Ultraviolet (SBUV) instrument. TOMS was a satellite-borne instrument that measured the total column amount of ozone in the atmosphere by measuring the ultraviolet (UV) sunlight scattered from the atmosphere, while SBUV was a companion instrument that measured how that ozone was distributed with altitude. The TOMS instrument measured the backscattered UV radiation at six wavelengths from 312 to 380 nm. By comparing light at a wavelength strongly absorbed by ozone to light at a wavelength weakly absorbed by ozone, an accurate measurement of ozone can be made. TOMS was a single monochromator with a scanning mirror that allowed the instrument to make measurements at 35 scan angles from left to right across the ground track of the satellite. TOMS was thus able to measure over the entire sunlit portion of the globe each day. The SBUV instrument was a double monochromator designed to measure backscattered radiation at 12 wavelengths from 255 to 340 nm. Because the shorter wavelengths penetrate only to the upper stratosphere, these wavelengths can be used to deduce both the upper-stratospheric concentration profile of ozone and the total column amount of ozone, but only along the nadir track of the satellite.

The TOMS instrument on Nimbus 7 made measurements for more than 14 years. The instrument finally failed in May 1993. A second TOMS instrument was launched on the Russian Meteor 3 satellite in 1991. This cooperative project was the first time an American instrument was flown on a Soviet spacecraft. This instrument made total ozone measurements until the end of 1994. A third TOMS instrument was launched on the Japanese ADEOS satellite in 1996, but the satellite power array failed after only 7 months of operation. A fourth TOMS instrument was launched on the Earth Probe satellite, also in 1996. Designated EP-TOMS, it operated through December 2005. A final TOMS instrument, QuikTOMS, was lost in 2001 when it failed to achieve orbit.

The successor instrument to the TOMS series of instruments is the Ozone Monitoring Instrument (OMI) launched on the Aura spacecraft in July 2005. OMI, which was built by the Dutch for flight on Aura, is an imaging spectrometer that measures over the range of 270–500 nm. The Ozone Mapping Profiler Suite (OMPS) is also an imaging spectrometer, designed to continue the US program of ozone monitoring begun by TOMS and SBUV. OMPS was launched on the Suomi-NPP satellite in 2011.

A series of SBUV/2 instruments has been flown by the National Oceanic and Atmospheric Administration (NOAA) to monitor long-term changes in ozone. Instruments were flown on NOAA 9 (1985–98), NOAA 11 (1989–2000), NOAA 14 (1995–2006), NOAA 16 (2001–present), NOAA 17 (2002–13), NOAA 18 (2005–12), and NOAA 19 (2009–present).

The Theory of Ozone Measurement

TOMS and SBUV can measure ozone from space because ozone absorbs very strongly in the UV. By comparing a measurement at a wavelength strongly absorbed by ozone to one weakly absorbed by ozone, an accurate estimate of the amount of ozone in the atmosphere can be made from space. The instruments measure sunlight scattered by the atmosphere and reflected from clouds and the ground.

Rayleigh Scattering

Light from the Sun penetrates into the atmosphere, with most of the visible light reaching the ground. Light is scattered by the

molecules that make up the atmosphere in a process called Rayleigh scattering, named after Lord Rayleigh, who first described it in the late nineteenth century. The probability of Rayleigh scattering depends inversely on the fourth power of the wavelength (λ^{-4}). Thus, an UV photon of 300 nm wavelength is 16 times more likely to be scattered than a visible photon of 600 nm wavelength. This is why the sky is blue. When we look at the sky away from the Sun, blue light is much more likely to be scattered toward us than is red light.

Surface Reflection and Clouds

Radiation that does reach the ground can be absorbed or reflected by the surface. The probability of reflection depends on the nature of the surface. In the UV range, the Earth is a very poor reflector. The UV reflectivity of the ocean in the 300–350 nm region of the spectrum is only about 4%. Most land surfaces have similarly low reflectivities, no more than 5% except in desert areas. Only areas covered by ice and snow have very high reflectivities, reaching 90% in the Antarctic.

When clouds are present, radiation reaching them is reflected back to space with high efficiency. Cloud reflectivities can reach 80–90% for thick clouds. Solar radiation that is reflected by clouds does not pass through the part of the atmosphere below the cloud and has no opportunity to be absorbed by the ozone below the clouds. The TOMS measurement is thus a measurement of the ozone above the cloud layer. Fortunately, this is a small effect since 90% of the ozone in the atmosphere is in the stratosphere. Only part of the 10% of the ozone column in the troposphere will be masked by clouds. This amount can be estimated from climatology, so that the measurement can be transformed into a fairly accurate estimate of the total column of ozone in the atmosphere.

Aerosols

Aerosols (dust particles in the atmosphere) also scatter radiation, further adding to the atmosphere's overall reflectivity. Their scattering does not follow the λ^{-4} dependence of Rayleigh scattering but is close to a λ^{-1} dependence. This means that when dust is in the atmosphere, the sky appears more nearly white. Aerosols do not affect our ability to measure ozone. However, the multiple reflectivity wavelengths can be used to deduce some information about the properties of aerosols. Measurement of the deviations from the expected result for a Rayleigh-scattering atmosphere can be used to determine an aerosol index and used to track dust and smoke plumes (see the section [Some Results from TOMS Measurements](#)).

Ozone Absorption

Sunlight can be absorbed in the atmosphere by a variety of molecules. The principal absorber of UV light in the Earth's atmosphere is ozone. Absorption in the UV by ozone is so strong that a few parts per million of ozone remove all of the sunlight at wavelengths shorter than about 300 nm before they can reach the ground. We are thus provided with a shield from the high-energy radiation that could break important DNA bonds in living cells. The absorption of UV by ozone is the

property that we generally use to measure the amount of ozone in the atmosphere. From the ground, we can look upward and measure how much radiation reaches us at a wavelength that is absorbed by ozone. We can compare this to the radiation received at a nearby wavelength that is not absorbed by ozone to determine the amount of ozone that must be between us and the Sun. Such measurements have been used to measure ozone since the 1920s. From satellites, we can look down and measure the radiation that is scattered back out of the atmosphere through Rayleigh scattering and again compare the amount at an absorbed wavelength with an unabsorbed (or less absorbed) wavelength.

Description of the TOMS Retrieval Algorithm

TOMS measures UV light scattered from the atmosphere and the Earth and clouds. An algorithm is needed to infer ozone from these measurements. The instrument looks downward at the Earth but also uses a diffuser plate to look at direct sunlight before it enters the atmosphere. The basic measured quantity is the ratio of the backscattered radiance to the direct solar irradiance. This is usually expressed as the N -value, or logarithm of the ratio:

$$N = -100 \log \left(\frac{I_0}{F} \right) \quad [1]$$

where F is the solar irradiance at the particular wavelength and I_0 is the backscattered radiance. TOMS measures the light scattered from the Earth–atmosphere system (I_0) at a range of wavelengths, and measures F , the direct sunlight, by periodically deploying a reflective diffuser plate in front of the instrument.

Using the ratio of backscattered radiation to direct solar flux cancels some of the main instrumental errors; that is, the instrument throughput is the same for each measurement and cancels when the ratio is taken. The reflectivity of the diffuser plate affects the solar irradiance measurement, but not the backscattered radiance measurement. If a pair of wavelengths is used in the analysis, then the diffuser reflectivity can be canceled out in the ratio if that reflectivity is the same for both wavelengths. Thus, we form the pair N -value as in eqn [2].

$$\begin{aligned} N_p &= N(\lambda_1) - N(\lambda_2) \\ &= \log \left(\frac{I_{01}}{F_1} \right) - \log \left(\frac{I_{02}}{F_2} \right) \end{aligned} \quad [2]$$

These N -values reflect the effects of scattering, reflection, and absorption. [Figure 1](#) illustrates the dependence of the N -value on wavelength, clearly showing that an ozone signal can be derived from the data. The actual algorithm used for the TOMS retrieval uses a radiative transfer code based on the early work of Dave. Forward calculations are carried out for a matrix of parameters, including total ozone. These then form a lookup table that is interpolated to derive total ozone.

Description of the SBUV Retrieval Algorithm

SBUV is similar to TOMS but is used to measure the altitude distribution of ozone. Like TOMS, its measurements are used as

Figure 1 Illustration of the dependence of N -value on wavelength. The N -values for all of the TOMS measurements for 1 day (1 January 1985) within 1° of latitude of 35° N were averaged to make the plot. The linear straight line is fitted to the three longest wavelengths to illustrate an extrapolation to shorter wavelengths. The actual TOMS algorithm uses a full radiative transfer code to determine this extrapolation. The difference between the short-wavelength N -values and the extrapolation represents the absorption by ozone.

N -values, but covering wavelengths further into the UV range – 12 wavelengths from 250 to 400 nm. The key is that the very short wavelengths do not penetrate to the ground. At 255 nm, light penetrates to only about 50 km altitude; at 290 nm, light penetrates to 40 km; and 302 nm penetrates to 30 km. Thus, the SBUV wavelength scan is equivalent to an altitude scan of ozone. In the actual profile retrieval, the Rodgers optimal estimation technique varies a first-guess ozone profile until the set of measured N -values is matched.

TOMS and SBUV

Instruments

The TOMS instruments are single, fixed monochromators with exit slits at six near-UV wavelengths. The slit functions are triangular with a nominal 1 nm bandwidth. The order of individual measurements is determined by a chopper wheel. As it rotates, openings at different distances from the center of the wheel pass over the exit slits, allowing measurements at the different wavelengths. The order was not one of monotonically increasing or decreasing wavelength; instead, the wavelengths were interleaved to minimize the effect of spacecraft movement on the ozone retrieval. The advantage of the more modern OMI and OMPS instruments is that they measure the complete spectrum at one time rather than sequentially measuring six wavelengths.

A ground aluminum diffuser plate is deployed to reflect sunlight into the instrument for measurement of the solar irradiance. This diffuser plate was shared by TOMS and SBUV experiment on the Nimbus 7 satellite. It was normally deployed once a week for TOMS solar irradiance measurements, in addition to the SBUV deployments. On the Earth Probe TOMS, a triple diffuser was used to eliminate the problem of the diffuser darkening as it was exposed to UV light in space. One diffuser was used daily, another was used weekly,

and the third was used only a couple of times a year to serve as the clean reference.

SBUV is a double monochromator. Because light at a short wavelength like 270 nm is 1000 times weaker than light at a longer wavelength like 320 nm, scattered light within the instrument itself is a problem. By dispersing the light twice, this scattered light can be reduced. Over 32 s, SBUV scans from 250 to 400 nm in 12 steps. Because more light is needed to measure the weak signal at short wavelengths, SBUV only measures along the orbit track, rather than scanning from side to side as TOMS does to cover the entire Earth.

Orbit

The Nimbus 7, ADEOS, Earth Probe, Aura, and NPP satellites were all in Sun-synchronous polar orbits. The nearly circular orbit is oriented perpendicular to the plane of the Earth's orbit around the Sun such that the satellite comes over the South Pole of the Earth toward the Equator, crosses the Equator near local noon, and then passes over the North Pole onto the nightside of the Earth. The satellite crosses the Equator again on the nightside at near midnight local time. By the time the satellite comes back onto the dayside, the Earth has rotated for approximately 90 min, and the satellite passes over a point at the Equator that is 27° of latitude to the west of the previous orbit but, again, at local noon. In this way, the satellite orbits 15 times per day, fixed relative to the Sun, and the Earth rotates underneath so that the satellite sees the whole of the surface of the Earth within a 24-h period.

This is a qualitative description of the orbits. Actually, for the purpose of orbit stability, the satellite does not pass exactly over the pole. A Sun-synchronous orbit requires an orbital inclination of approximately 98° , which gives a maximum orbit latitude of about 80° . A slightly inclined orbit precesses just enough to stay exactly in the noon plane over the course of the year. From this orbit, TOMS can see the pole itself by

scanning to the far right or left. The Meteor 3 spacecraft was in a polar orbit but was not Sun synchronous. Its Equator-crossing time drifted from near noon to near sunset and back to near noon in a 220-day cycle. The NOAA series of satellites carrying SBUV/2 instruments were also in Sun-synchronous orbits, but ones that drifted slowly away from noon over a few years.

Geometry and Timing

The instrument field of view for TOMS is $3 \times 3^\circ$. At an altitude of 950 km for Nimbus 7, this projects to a nadir spot size on the surface of $50 \text{ km} \times 50 \text{ km}$. Earth Probe was launched initially into a 500 km orbit, which resulted in a nadir spot size of 26 km. In December 1997, it was boosted to an altitude of 740 km, increasing the nadir spot size to 40 km.

For each of the TOMS instruments, a mirror scans perpendicular to the orbital plane in 35 steps of 3° . The scan angles range from 51° on the right side of the spacecraft nadir to 51° on the left (relative to the direction of flight). At the end of the scan, the mirror returns to the first position and begins another scan. For Nimbus 7, the cross-track scans from consecutive orbits overlapped, creating a completely filled global map of the sunlit part of the Earth each day. The lower altitude of the Earth Probe TOMS results in small areas between orbits near the Equator where no measurements are

made (as in Figure 2). The location of these gaps shifts from day to day so that no place fails to be measured over the span of a few days.

During the cross-track scan, each of the 35 measurement locations is observed for 200 ms. The total duration time for a single scan is 7.8 s, during which time the satellite travels approximately 40 km. One orbit consists of nearly 400 cross-track scans or 13 000 measurements. Fifteen orbits result in about 190 000 measurements of total ozone every day. SBUV is similar to TOMS but does not scan. SBUV looks only at a 200 km square field of view directly beneath the spacecraft.

The imaging instruments, OMI and OMPS, project an entire strip of the Earth onto a charge-coupled device (CCD) detector. As the satellite moves, this strip maps out the Earth. This is known as a push-broom system. The image on the CCD consists of the strip of the Earth below the satellite (imaged in the x direction) and the wavelength (imaged in the y direction).

Some Results from TOMS Measurements

Ozone Maps

The original purpose for building TOMS was its capability to map global ozone on a daily basis to help understand its relationship to changes in the meteorology of the atmosphere.

Figure 2 Global ozone mapped by TOMS on 16 March 1979, soon after launch. Note regions of very high ozone in the Arctic and low ozone near the Equator.

The problem of the relationship of total ozone to meteorology goes back to Dobson in the 1920s. Dobson had six of his spectrophotometers built and distributed throughout Europe to examine this problem. He found that when a high-pressure system was present, ozone was low; and when a low-pressure system was present, ozone was high. TOMS was designed to map the entire sunlit portion of the globe in a single day (Figure 2).

When the discovery of the ozone hole was announced in 1985, TOMS was immediately used to map the extent of the ozone-depleted region (Figure 3). Using TOMS, the daily progress of the hole could be followed. These maps demonstrated that the ozone-depleted region rotated around the pole, was distorted by the meteorology, and was finally broken up by a series of wave events that eroded the polar vortex. TOMS can produce similar maps of ozone over the Arctic polar region (not shown). The maps clearly demonstrate the day-to-day and year-to-year variability of ozone over the Arctic. As global warming changes the dynamics of the atmosphere, such maps will show the effect on the global ozone distribution.

Ozone Trends

While the Nimbus 7 TOMS instrument was originally designed to map ozone on a daily basis to study day-to-day variability in

total ozone, by the 1990s TOMS data were also being used as part of a satellite-based measurement system for detecting long-term trends in stratospheric ozone. A number of features in the TOMS measurements made it possible to detect calibration drifts of the instrument well enough that small changes in ozone could be detected – trends as small as 1% per decade (2 Sigma).

More recently, a unified long-term time series of global ozone, a Merged Ozone Data Set, has been created using data from multiple SBUV instruments. Data from the series of nine National Aeronautics and Space Administration and NOAA SBUV/2 instruments were reprocessed with a coherent calibration covering the period 1970–72 and 1979–2012. The advantage of concentrating on SBUV instruments is the long time span covered by instruments of similar design and their high accuracy. Because the profile retrieval uses wavelengths that have high sensitivity to ozone, the total column ozone derived by integrating the retrieved profile is estimated to have accuracy better than 1%.

Figure 4 compares ozone measured by satellite instruments since 1979 with that measured by ground-based instruments in Arosa, Switzerland, since 1926. This puts the current ozone decrease in the context of the historical record and emphasizes that both satellites and ground-based instruments are seeing the same ozone changes. Satellite instruments are necessary

Figure 3 Single-day (5 October 2000) ozone map over the Antarctic. Dark blue to purple shades near pole indicate where total ozone amount is less than 220 DU, a common definition for the region of the Antarctic ozone hole. The map is a polar orthographic projection with the South Pole at the center and the equator at the outer boundary.

Figure 4 The long-term change in ozone as measured by a series of satellite instruments (in red) compared with ozone measured by ground-based instruments in Switzerland (in blue) since 1926.

to measure global ozone change and show that such ozone decreases are not a local phenomenon.

Dust and Smoke

TOMS measures the reflectivity of the Earth–atmosphere system at several wavelengths not absorbed by ozone. If the atmosphere were perfectly clean, the backscattered radiation received by the satellite could be determined from a Rayleigh-scattering calculation that would predict a specific ratio of radiation between two wavelengths. Aerosols disturb this ratio in a predictable manner: one direction for absorbing aerosols, and the opposite for nonabsorbing aerosols. Using these facts, the TOMS data have been used to determine an ‘aerosol index.’ Reasonable assumptions about the nature of the aerosols lead to global maps of the spread of dust from deserts and smoke from biomass burning in Africa and South America. There are now 40 years’ worth of such data from the TOMS instruments and now OMI and OMPS.

Figure 5 is a map of the aerosol index for 10 March 2006, showing dust from deserts in China being carried across the Pacific. Similar maps are used to track dust from the Sahara Desert crossing the Atlantic Ocean, smoke from forest fires, and ash from volcanoes.

Reflectivity

The basic TOMS measurement is of reflected radiation at six wavelengths. The longer of these wavelengths are not affected by ozone absorption and are thus a measure of the reflectivity of the atmosphere in the UV. The algorithm calculates the expected backscattered radiation from a pure Rayleigh-scattering atmosphere. Deviations from this expectation are driven primarily by clouds and secondarily by aerosols. The deviations caused by clouds, which are different spectrally than the deviations caused by aerosols, can be represented as a percentage reflectivity.

The scene reflectivity of the Earth at blue and UV wavelengths is low over most surfaces (except ice and snow), and are almost independent of the seasonal changes in vegetation on land and in the oceans. This makes it ideal for examining changes in radiation reflected back to space from

changes in cloud and aerosol amounts, especially as affected by the start of climate change. The aerosol index shown in **Figure 5** (in color) is overlaid onto a map of cloud reflectivity (white).

Volcanoes

When a volcano erupts, it releases large quantities of ash and sulfur dioxide (SO_2), both of which can be mapped by TOMS, OMI, and the OMPS total column mapper. SO_2 is an even stronger absorber of UV light than ozone, but with a very different spectral signature. When El Chichon erupted in 1982, SO_2 absorption produced a false apparent enhancement of TOMS ozone. When this was realized, the TOMS algorithm was modified to distinguish ozone from SO_2 . **Figure 6** shows a plume of SO_2 from the eruption of the Grimsvotn volcano in Iceland on 21 May 2011. TOMS (and OMI and OMPS) can easily track plumes of SO_2 from volcanic eruptions. The effect of SO_2 from a volcano is usually short lived because SO_2 is converted rapidly to sulfuric acid aerosols. Because they have full spectral data, OMI and OMPS can even detect SO_2 from power plants and other pollution sources in the lower troposphere.

UV at Surface

Many of the concerns about ozone depletion are related to the increase in UV radiation received at the surface of the Earth. Increases in UV would lead to increased incidence in skin cancer (among humans) and possible damage to the biosphere. TOMS measures the outgoing, absorbed UV radiation and the reflectivity due to clouds and aerosols. These data can be combined with a radiative transfer model to estimate the UV flux at the surface daily across the globe. TOMS and OMI data have been used to generate detailed maps of average UV flux over the Earth.

Tropospheric Ozone

TOMS measures the total column amount of ozone with some adjustments for the inefficiency of the penetration of UV sunlight into the boundary layer. In the tropics, most of the

Figure 5 Aerosol index measured by an OMI on 10 March 2006 showing dust blowing out of deserts in China. Here, aerosol index is mapped (in color) with reflectivity over a world map.

variability of total ozone around a circle of constant latitude is in the troposphere rather than the stratosphere. Several schemes have been developed for taking advantage of this property of the total ozone measurements to derive tropical tropospheric ozone column amounts. The first of these combined the TOMS measurements with concurrent measurements from the Stratospheric Aerosol and Gas Experiment (SAGE) occultation measurements of the stratospheric amount. The difference between TOMS total column ozone and SAGE stratospheric ozone will be the amount of ozone in the troposphere. Similarly, OMI measurements of ozone have been combined with ozone profile measurements by the microwave limb sounder, also on the Aura spacecraft, to give very accurate measurements of tropospheric ozone. Alternatively, the stratospheric ozone amount can be estimated directly from TOMS measurements above the location of the highest clouds. That amount can be subtracted from the total ozone measured in clear areas, yielding a tropical map of column tropospheric ozone.

Application of these techniques for deriving tropical tropospheric ozone gives maps showing the ozone generated

by the products of biomass burning. The ozone development and transport can be seen far downwind from the burning source.

Summary and Future of TOMS and SBUV Measurements

We now have more than 40 years' worth of global total ozone data from TOMS instruments, and ozone profile measurements from SBUV. The Earth Probe TOMS was the last of the series, but OMI on Aura and the OMPS total column mapper have continued the measurement series. The SBUV/2 instrument on NOAA 19 is the last of the SBUV series, but the OMPS nadir profiler continues the ozone profile measurements. OMI and the OMPS instruments represent a new generation of ozone-mapping instruments, instruments that use CCD arrays to image the Earth at a large number of wavelengths. These instruments allow us to continue the long time series of ozone measurements to document the expected recovery of the Earth's ozone layer.

Figure 6 An OMI map of sulfur dioxide shows that SO_2 from the 21 May 2011 eruption of the Grimsvotn volcano in Iceland has been transported over Greenland 2 days later.

Introduction

To fully understand and use data from meteorological satellites, it is necessary to understand the orbits in which satellites are constrained to move and the geometry with which they view the Earth. This article begins with a review of basic physical principles, which reveal the shape of a satellite orbit and how to orient the orbital plane in space. This knowledge allows us to calculate the position of a satellite at any time. Orbit perturbations and their effects on satellite orbits are then discussed. Finally, the geometry of satellite tracking and Earth location of the measurements made from the satellites are explored.

Newton's Laws

Isaac Newton discovered the basic principles that govern the motions of satellites and other heavenly bodies.

Newton's Laws of Motion

1. Every body will continue in its state of rest or of uniform motion in a straight line except insofar as it is compelled to change that state by an impressed force.
2. The rate of change of momentum is proportional to the impressed force and takes place in the line in which the force acts.
3. Action and reaction are equal and opposite.

Since momentum is the product of the mass of a body and its velocity, Newton's second law is the familiar eqn [1], where F is force, m is mass, a is acceleration, v is velocity, and t is time.

$$F = ma = m \frac{dv}{dt} \quad [1]$$

In addition, Newton gave us the functional form of the force that determines satellite motion in the law of gravitation.

Newton's Law of Universal Gravitation

The force of attraction between two point masses m_1 and m_2 separated by a distance r is given by eqn [2], where G is the Newtonian (or universal) gravitation constant ($6.67259 \times 10^{-11} \text{ N m}^2 \text{ kg}^{-2}$).

$$F = \frac{Gm_1m_2}{r^2} \quad [2]$$

Consider the simple circular orbit shown in Figure 1. Assuming that the Earth is a sphere, we can treat it as a point mass. The centripetal force required to keep the satellite in a circular orbit is mv^2/r , where v is the orbital velocity of the satellite. The force of gravity that supplies this centripetal force is Gm_em/r^2 , where m_e is the mass of the Earth

($5.97370 \times 10^{24} \text{ kg}$) and m is the mass of the satellite. Equating the two forces gives eqn [3].

$$\frac{mv^2}{r} = \frac{Gm_em}{r^2} \quad [3]$$

Division by m eliminates the mass of the satellite from the equation, which means that the orbit of a satellite is independent of its mass. The period of the satellite is the circumference of the orbit divided by the velocity (eqn [4]).

$$T = \frac{2\pi r}{v} \quad [4]$$

Substituting eqn [4] in eqn [3] gives eqn [5] for the period.

$$T^2 = \frac{4\pi^2}{Gm_e} r^3 \quad [5]$$

A typical weather satellite orbits 833 km above the Earth's surface. Since the equatorial radius of the Earth is 6378.137 km, the orbit radius is about 7211 km. Substituting in eqn [5] yields a period of about 6094 s or 102 min.

As a second example, we calculate the radius required for a satellite in geosynchronous orbit, that is, an orbit in which the satellite has the same angular velocity as the Earth ($7.292115 \times 10^{-5} \text{ rad s}^{-1}$). The angular velocity of a satellite is given by eqn [6].

$$\xi = \frac{2\pi}{T} \quad [6]$$

Substituting eqn [6] in eqn [5] gives eqn [7] for the radius.

$$r^3 = \frac{Gm_e}{\xi^2} \quad [7]$$

Figure 1 A circular satellite orbit.

Therefore, the required radius for a geosynchronous orbit is about 42 164 km, or about 35 786 km above the Earth's surface.

Keplerian Orbits

Although a circular orbit is the goal for most meteorological satellites, in general satellites do not travel in perfect circles. The exact form of a satellite's orbit may be derived from Newton's laws of motion and the law of universal gravitation. The results of this derivation are neatly summarized in Kepler's laws and in Kepler's equation.

Kepler's Laws

Johannes Kepler died 12 years before Newton was born and, thus, did not have the advantage of Newton's work. Kepler formulated his laws by analyzing data on the position of the planets. This task was complicated by the rotation of the Earth and the motion of the Earth about the Sun, which make planetary motions seem very complex. In modern form, Kepler's laws may be stated as follows.

1. All planets travel in elliptical paths with the Sun at one focus.
2. The radius vector from the Sun to a planet sweeps out equal areas in equal times.
3. The ratio of the square of the period of revolution of a planet to the cube of its semimajor axis is the same for all planets revolving around the Sun.

The same laws apply if we substitute satellite for planet and Earth for Sun. Equation [5] is a statement of Kepler's third law for the special case of a circular orbit.

Ellipse Geometry

The parameters that are used to specify satellite orbits are based in part on geometric terminology. Figure 2 illustrates the geometry of an elliptical orbit. The point where the satellite most closely approaches the Earth is termed the perigee, or more generally the perifocus. The point where the satellite is farthest from the Earth is called the apogee or apofocus. The

distance from the center of the ellipse to the perigee (or apogee) is the semimajor axis (denoted by the symbol a). The distance from the center of the ellipse to one focus (to the center of the Earth) divided by the semimajor axis is the eccentricity (ϵ). For an ellipse, the eccentricity is a number between zero and 1 ($0 < \epsilon < 1$). A circle is an ellipse with zero eccentricity. The equation for the ellipse, that is, the path that the satellite follows, is given in polar coordinates with the center of the Earth as origin by eqn [8].

$$r = \frac{a(1 - \epsilon^2)}{1 + \epsilon \cos \theta} \quad [8]$$

The angle θ (see Figure 3) is the 'true anomaly' and is always measured counterclockwise (the direction of satellite motion) from the perigee.

Kepler's Equation

A satellite in a circular orbit has uniform angular velocity. By Kepler's second law, however, a satellite in an elliptical orbit cannot have uniform angular velocity; it must travel faster

Figure 3 The geometric relationship between true anomaly (θ) and eccentric anomaly (e).

Figure 2 Elliptical orbit geometry.

Figure 4 The right ascension–declination coordinate system.

when it is closer to the Earth. The position of the satellite as a function of time can be found by applying Kepler's equation as eqn [9].

$$M = n(t - t_p) = M_0 + n(t - t_0) = e - \varepsilon \sin e \quad [9]$$

Here M is the mean anomaly, an angle that increases linearly in time at the rate n , called the mean motion constant, given by eqn [10].

$$n = \frac{2\pi}{T} = \sqrt{\frac{Gm_e}{a^3}} \quad [10]$$

By definition, M is zero when the satellite is at perigee; therefore, t_p is the time of perigee passage. Time t_0 is called the epoch time. M_0 is called the mean anomaly true of epoch, that is, the mean anomaly at the epoch time t_0 . The angle e is the eccentric anomaly. It is geometrically related to the true anomaly (Figure 3) through eqns ([11a] and [11b]).

$$\cos \theta = \frac{\cos e - \varepsilon}{1 - \varepsilon \cos e} \quad [11a]$$

$$\cos e = \frac{\cos \theta + \varepsilon}{1 + \varepsilon \cos \theta} \quad [11b]$$

Given a , ε , and t_p (or M_0 and t_0), one can calculate r and θ at any time t using eqns ([8], [9], [10], [11a] and [11b]).

Orientation in Space

By calculating r and θ at time t , we have positioned the satellite in the plane of its orbit. Now we must position the orbital plane in space. To do this requires the definition of a coordinate system. This coordinate system must be an inertial coordinate system, that is, a nonaccelerating system in which Newton's laws of motion are valid. A coordinate system fixed to the rotating Earth is not such a system. We will adopt an

astronomical coordinate system called the right ascension–declination coordinate system.¹ In this system (Figure 4), the z -axis is aligned with the Earth's spin axis. The x -axis is chosen such that it points from the center of the Earth to the Sun at the moment of the vernal equinox, when the sun is crossing the equatorial plane from the Southern Hemisphere to the Northern Hemisphere.² The y -axis is chosen so as to make it a right-handed coordinate system. In this system, the declination of a point in space is its angular displacement measured northward from the equatorial plane, and the right ascension is the angular displacement, measured counterclockwise from the x -axis, of the projection of the point in the equatorial plane (Figure 5).

Three angles are used to position an elliptical orbit in the right ascension–declination coordinate system: the inclination angle, the right ascension of ascending node, and the argument of perigee (Figure 6).

The inclination angle (i) is the angle between the equatorial plane and the orbital plane. By convention, the inclination angle is zero if the orbital plane coincides with the equatorial plane and if the satellite rotates in the same direction as the Earth. If the two planes coincide but the satellite rotates opposite to the Earth, the inclination angle is 180° . Prograde orbits are those with inclination angles less than 90° ; retrograde orbits are those with i greater than 90° .

¹ Because the origin of this coordinate system moves about the Sun with the Earth, it is not truly inertial. However, the Sun's gravity causes the satellite to rotate around the Sun as does the Earth. Therefore, the satellite acts as if the right ascension–declination coordinate system were inertial.

² This x -axis is also referred to as the First Point of Aries because it used to point at the constellation Aries. Because of the influence of the Sun and Moon on the nonspherical Earth, the Earth's spin axis precesses like a top with a period of 25 781 years. This causes the vernal equinox to change. Today, the x -axis points to the constellation Pisces, but it is still referred to as the First Point of Aries.

Figure 5 Coordinates used in the right ascension–declination coordinate system: right ascension (Ω), declination (δ), and radius (r).

The ascending node is the point where the satellite crosses the equatorial plane going north (ascends). The right ascension of this point is the right ascension of ascending node (Ω). It is measured in the equatorial plane from the x -axis (vernal equinox) to the ascending node. In practice, the right ascension of ascending node has a more general meaning. It is the right ascension of the intersection of the orbital plane with the equatorial plane; thus, it is always defined, not just when the satellite is actually at an ascending node.

Finally, the argument of perigee (ω) is the angle measured in the orbital plane between the ascending node (equatorial plane) and the perigee.

Orbital Elements

The parameters just discussed for locating a satellite in space are collectively known as the classical orbital elements; they

Table 1 Classical Orbital elements

Element	Symbol
Semimajor axis	a
Eccentricity	e
Inclination	i
Argument of perigee	ω_0
Right ascension of ascending node	Ω_0
Mean anomaly	M_0
Epoch time	t_0

are summarized in [Table 1](#). These parameters may be determined by optical, radar, or radio ranging observations. They are carefully determined by various agencies and are available over the Internet for most satellites. There is some variation in how the orbital elements are specified. Some agencies, for example, substitute true anomaly for mean anomaly. Also, in less formal descriptions of satellite orbits, the height of the satellite above the Earth's surface is substituted for the semimajor axis. Since the Earth is not round, the height of a satellite varies according to its position in the orbit. Such heights are converted into semimajor axis by adding the equatorial radius of the Earth.

Orbits in which the classical orbital elements (except M) are constant are called Keplerian orbits. Viewed from space, Keplerian orbits are simple. The satellite moves in an elliptical path with the center of the Earth at one focus. The ellipse maintains a constant size, shape, and orientation with respect to the stars ([Figure 7](#)). Perhaps surprisingly, the only effect of the Sun's gravity on the satellite is to move the focus of the ellipse (the Earth) in an elliptical path around the Sun (the Earth's orbit).

Viewed from the earth, Keplerian orbits appear complicated because the Earth rotates on its axis as the satellite orbits the Earth ([Figure 8](#)). The rotation of the Earth beneath a fixed orbit results in two daily passes of the satellite near a point on the Earth (assuming that the period is substantially less than a day and that the inclination angle is greater than the latitude of the point). One pass occurs during the ascending portion of the orbit; the other occurs during the descending portion of

Figure 6 Angles used to orient an orbit in space.

Figure 7 The change with season of a Keplerian orbit.

Figure 8 The orbit of a representative satellite as viewed from a point rotating with the Earth.

the orbit. This usually means that one pass occurs during daylight and one during darkness.

Orbit Perturbations

Although satellites travel in nearly Keplerian orbits, these orbits are perturbed by a variety of forces (Table 2). Forces arising from the last five processes are small and can be viewed as causing essentially random perturbations in the Orbitally they are dealt with simply by periodically (1) observing the orbital elements and (2) adjusting the orbit with on-board thrusters. Forces due to the nonsphericity of the Earth cause secular (linear with time) changes in some of the orbital

Table 2 Orbit-perturbing forces

Force	Source
Nonspherical gravitational field	Nonspherical, nonhomogeneous earth
Gravitational attraction of auxiliary bodies	Moon, planets
Radiation pressure	Sun's radiation
Particle flux	Solar wind
Lift and drag	Residual atmosphere
Electromagnetic forces	Interaction of electrical currents in the satellite with the earth's magnetic field

elements. These changes can be predicted theoretically and indeed are useful.

The gravitational potential of the Earth is a complicated function of the Earth's shape, the distribution of land and ocean, and the density of crustal material. As a first-order correction to a spherical shape, we may treat the Earth as an oblate spheroid of revolution. In cross-section, the Earth is approximately elliptical. The distance from the center of the Earth to the Equator is, on average, 6378.137 km, whereas the distance to the poles is 6356.752 km. The gravitational potential of the Earth is given approximately by eqn [12], where r_{ee} is the equatorial radius of the earth, δ is the declination angle, and J_2 (1.08263×10^{-3}) is the coefficient of the quadrupole term.

$$U = -\frac{Gm_e}{r} \left[1 + \frac{1}{2} J_2 \left(\frac{r_{ee}}{r} \right)^2 (1 - 3 \sin^2 \delta) + \dots \right] \quad [12]$$

The higher-order terms are more than two orders of magnitude smaller than the quadrupole term and will not be considered here, although they are necessary for very accurate calculations.

A satellite travels at a slightly different speed in this gravitationally perturbed orbit. The time rate of change of the mean anomaly is given by the mean motion constant (n) in the unperturbed orbit and by the anomalistic mean motion constant ($\bar{n}$) in a perturbed orbit. Considering only the quadrupole term we have eqn [13].

$$\frac{dM}{dt} = \bar{n} = n \left[1 + \frac{3}{2} J_2 \left(\frac{r_{ee}}{a} \right)^2 (1 - \epsilon^2)^{-3/2} (1 - \frac{3}{2} \sin^2 i) \right] \quad [13]$$

When the inclination angle is less than 54.7° or greater than 125.3° , $\bar{n}$ is greater than n , and the satellite orbits faster than it would in an unperturbed orbit. For inclination angles between 54.7° and 125.3° , the satellite orbits more slowly than it otherwise would.

The rate of change of the right ascension of ascending node is given by eqn [14].

$$\frac{d\Omega}{dt} = -\bar{n} \left[\frac{3}{2} J_2 \left(\frac{r_{ee}}{a} \right)^2 (1 - \epsilon^2)^{-2} \cos i \right] \quad [14]$$

The rate of change of the argument of perigee is given by eqn [15].

$$\frac{d\omega}{dt} = \bar{n} \left[\frac{3}{2} J_2 \left(\frac{r_{ee}}{a} \right)^2 (1 - \epsilon^2)^{-2} \left(2 - \frac{5}{2} \sin^2 i \right) \right] \quad [15]$$

The other three orbital elements, a , ϵ , and i , undergo small, oscillatory changes that may be neglected.

The anomalistic period of a perturbed orbit is simply that given by eqn [16].

$$\bar{T} = \frac{2\pi}{\bar{n}} \quad [16]$$

However, because M is measured from perigee, the anomalistic period is the time for the satellite to travel from perigee to moving perigee. Of more use is the synodic or nodal period, $\tilde{T}$, which is the time for the satellite to travel from one ascending node to the next ascending node. An exact value of $\tilde{T}$ must be calculated numerically; however, eqn [17] holds to very good approximation.

$$\tilde{T} = \frac{2\pi}{\bar{n} + (d\omega/dt)} \quad [17]$$

In summary, the first-order effects of the nonspherical gravitational potential of the Earth consist of a slow, linear change in two of the classical orbital elements, the right ascension of ascending node and the argument of perigee, and a small change in the mean motion constant. Table 3 shows orbital elements for some representative satellites.

Meteorological Satellite Orbits

Nearly all meteorological satellites are in one of two orbits, Sun-synchronous or geostationary, but other orbits are also useful.

Sun-Synchronous Orbits

As shown in Figure 7, in a Keplerian orbit the angle between the Sun and the plane of a satellite's orbit changes because the orbital plane is fixed while the Earth rotates around the Sun. This causes the satellite to pass over an area at different times of the day. For example, if the satellite passes over near noon (1200) and midnight (2400) in the spring, it will pass over near 0600 and 1800 in the winter. Fortunately, the perturbations

caused by the nonspherical earth can be employed to keep the Sun–Earth–satellite angle nearly constant.

The Earth makes one complete revolution about the Sun (2π radians) in one tropical year (31 556 925.9747 s). Thus, the right ascension of the Sun changes at the average rate of $1.991064 \times 10^{-7} \text{ rad s}^{-1}$ ($0.9856473^\circ \text{ day}^{-1}$). If the inclination of the satellite is correctly chosen, the right ascension of its ascending node can be made to precess at this rate. An orbit that is so synchronized with the Sun is called a Sun-synchronous orbit. For a satellite with a semimajor axis of 7221 km and zero eccentricity, eqn [14] requires an inclination of 98.75° to be Sun-synchronous. Figure 9 shows the change with season of a Sun-synchronous orbit.

Figure 9 The change with season of a Sun-synchronous orbit.

Table 3 Orbital elements of representative satellites

Satellite					Right ascension of ascending node		Argument of perigee		Mean anomaly		Nodal period (min)

Epoch time = 0000 UTC 6 September 2000.

The subsatellite point is the point on the Earth's surface that is directly between the satellite and the center of the Earth. The ground track of a satellite is the path of the subsatellite point. **Figure 10** shows the ground track for three orbits of the Sun-synchronous NOAA 11 satellite.

Geostationary Orbits

Earlier we calculated the radius of a geosynchronous orbit to be 42 164 km. Perturbations due to the nonspherical Earth, however, require a slight adjustment in this figure. The adjustment is small because the radius of geosynchronous orbit is about 6.6 Earth radii and the correction terms are inversely proportional to the square of this ratio. For a geosynchronous orbit with zero eccentricity and zero inclination, eqns [6], [13], [15] and [17] require a semimajor axis of 42 166.3 km.

The terms geosynchronous and geostationary are often used interchangeably. In fact, they are not the same. Geosynchronous means that the satellite orbits with the same angular velocity as the Earth. A geostationary orbit is geosynchronous, but it is also required to have zero inclination angle and zero eccentricity. Geostationary satellites, therefore, remain essentially motionless above a point on the Equator. They are classified by the longitude of their subsatellite point.

Second-order perturbations cause a geostationary satellite to drift from the desired orbit. Periodic maneuvers, performed as frequently as once a week, are required to correct the orbit. These maneuvers keep operational geostationary satellites very close to the desired orbit.

Figure 11 shows the ground track of a typical geostationary satellite.

Other Orbits

Geostationary and Sun-synchronous are only two of an infinity of possible orbits. Others have been and will become useful for meteorological satellites.

The Earth Radiation Budget Satellite (ERBS) was launched from the Space Shuttle and orbits at an altitude of 600 km with an inclination angle of 57° . It was placed in this orbit so that it would precess with respect to the Sun and sample all local times over the course of a month.

Figure 11 The ground track of a typical geostationary satellite (ten orbits of GOES 8).

Meteor satellites fly in low Earth orbit with inclination angles of about 82° . Molniya communications satellites fly in highly elliptical orbits. It has been suggested that this orbit would be useful for meteorological observations of the high latitudes. The Molniya orbit has an inclination angle of 63.4° , at which the argument of perigee is motionless; thus, the apogee, from which measurements are made, stays at a given latitude. The semimajor axis is chosen such that the satellite makes two orbits while the Earth turns once with respect to the plane of the orbit. The eccentricity is made as large as possible so that the satellite will stay near apogee longer. However, the eccentricity must not be so large that the satellite encounters significant atmospheric drag at perigee. A semimajor axis of 26 554 km and an eccentricity of 0.72 result in a perigee of 7378 km (1000 km above the Equator), an apogee of 45 730 km (39 352 km above the Equator), and a period of 717.8 min. The attractiveness of this orbit is that it functions as a high-latitude, part-time, nearly geostationary satellite. For about 8 h centered on apogee, the satellite is synchronized with the Earth so that it is nearly stationary in the sky. For a meteorological satellite in a Molniya orbit, the rapid imaging

Figure 10 The ground track of a typical Sun-synchronous satellite (three orbits of NOAA 15).

capability, which is so useful from geostationary orbit, would be available in the high latitudes.

As meteorological satellite instruments become more specialized, more custom orbits are likely to be used.

Satellite Positioning, Tracking, and Navigation

It is important to be able to calculate the position of a satellite in space, to track it from Earth, and to know where its instruments are pointing. These topics are discussed in turn in this section.

Positioning in Space

To locate a satellite in a perturbed orbit at time t , one needs current values of the orbital elements. The three constant elements, a , e , and i , are taken directly from a recent bulletin. Such bulletins are available from a variety of sources, and many are available on the Internet. The other three, M , Ω , and ω , are calculated according to eqns ([18a], [18b] and [18c])

$$M = M_0 + \frac{dM}{dt}(t - t_0) \quad [18a]$$

$$\Omega = \Omega_0 + \frac{d\Omega}{dt}(t - t_0) \quad [18b]$$

$$\omega = \omega_0 + \frac{d\omega}{dt}(t - t_0) \quad [18c]$$

Next, the satellite is located in the plane of its orbit; that is, the true anomaly θ and the radius r are calculated. This is done

by (1) solving for e using Kepler's equation [9]; (2) calculating θ using eqn [11a]; and (3) calculating r using eqn [8]. (For a circular orbit, this step is simplified because the mean anomaly, the eccentric anomaly, and the true anomaly are identical, and r is constant.)

A vector can now be constructed that points from the center of the Earth to the satellite in the right ascension–declination coordinate system. The Cartesian coordinates of this vector are given by eqn [19].

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} r \cos \theta \\ r \sin \theta \\ 0 \end{pmatrix} \quad [19]$$

At this point, the orbital ellipse is assumed to lie in the x - y plane (the equatorial plane) with the perigee on the positive x -axis (Figure 12(a)).

In the next three steps, the vector is rotated so that the orbital plane is properly oriented in space. First, the vector is rotated about the z -axis through the argument of perigee (Figure 12(b)). This rotation is conveniently accomplished by multiplying the vector by a rotation matrix (eqn [20]).

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = \begin{pmatrix} \cos \omega & -\sin \omega & 0 \\ \sin \omega & \cos \omega & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} \quad [20]$$

$$= \begin{pmatrix} x \cos \omega - y \sin \omega \\ x \sin \omega + y \cos \omega \\ z \end{pmatrix}$$

Figure 12 Rotations used to position a satellite in its orbit: (a) the satellite in the plane of its orbit; (b) rotation about the z -axis through the argument of perigee (ω); (c) rotation about the x -axis through the inclination angle (i); and (d) rotation about the z -axis through the right ascension of ascending node (Ω).

Second, the vector is rotated about the x -axis through the inclination angle (Figure 12(c)) as in eqn [21].

$$\begin{aligned} \begin{pmatrix} x'' \\ y'' \\ z'' \end{pmatrix} &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos i & -\sin i \\ 0 & \sin i & \cos i \end{pmatrix} \begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} \\ &= \begin{pmatrix} x' \\ y' \cos i - z' \sin i \\ y' \sin i + z' \cos i \end{pmatrix} \end{aligned} \quad [21]$$

Third, the vector is rotated about the z -axis through the right ascension of the ascending node (Figure 12(d)) as in eqn [22].

$$\begin{aligned} \begin{pmatrix} x''' \\ y''' \\ z''' \end{pmatrix} &= \begin{pmatrix} \cos \Omega & -\sin \Omega & 0 \\ \sin \Omega & \cos \Omega & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x'' \\ y'' \\ z'' \end{pmatrix} \\ &= \begin{pmatrix} x'' \cos \Omega - y'' \sin \Omega \\ x'' \sin \Omega + y'' \cos \Omega \\ z'' \end{pmatrix} \end{aligned} \quad [22]$$

The vector (x''', y''', z''') is the location of the satellite in the right ascension–declination coordinate system at time t . This vector may be converted into the radius, declination, and right ascension of the satellite through eqns [23a], [23b] and [23c].

$$r_s = \sqrt{x'''^2 + y'''^2 + z'''^2} = r \quad [23a]$$

$$\delta_s = \sin^{-1} \left(\frac{z'''}{r_s} \right) \quad [23b]$$

$$\Omega_s = \tan^{-1} \left(\frac{y'''}{x'''} \right) \quad [23c]$$

Finally, it is useful to calculate the latitude and longitude of the subsatellite point. Assuming that the Earth is a sphere, the latitude (known as the geocentric latitude) is simply equal to the declination (eqn [24]).

$$\text{Geocentric latitude} = \varphi_s = \delta_s \quad [24]$$

For more precise measurements, the latitude corrected for the nonspherical shape of Earth (the geodetic latitude) is usually used (eqn [25]).

$$\begin{aligned} \text{Geodetic latitude} &= \varphi_g \\ &= \tan^{-1} \left[\left(\frac{r_{ee}}{r_{ep}} \right)^2 \tan \delta_s \right] \end{aligned} \quad [25]$$

where r_{ep} is the polar radius of the Earth. The longitude of the subsatellite point (λ_s) is the difference between the right ascension of the satellite and the right ascension of the prime meridian (0° longitude), which passes through Greenwich, England (Figure 13) (eqn [26]).

$$\lambda_s = \Omega_s - \Omega_{\text{Greenwich}} \quad [26]$$

The right ascension of Greenwich is given in some satellite bulletins, and it can be calculated from eqn [27], where Δt is the time difference in days from 0000 UTC 1 January 2000.

$$\Omega_{\text{Greenwich}} = 99.9643^\circ + 360.9856376^\circ \Delta t \quad [27]$$

Since the rotation rate changes very slightly, owing to the actions of the wind and ocean currents, eqn [27] must be updated periodically.

Figure 13 The relationship between Earth longitude and right ascension.

The inverse problem of finding when a satellite passes over (or close to) a particular point is solved iteratively by (1) estimating the time, (2) calculating the position of the satellite, and (3) correcting the time estimate. Steps 2 and 3 are repeated until a satisfactory solution is found.

The above method can be streamlined in two ways. First, some of the rotations can be combined. Start as above by updating the orbital elements and calculating r_s and θ at time t . Locate the satellite on the x -axis at distance r_s from the center of the Earth (eqn [28]).

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} r_s \\ 0 \\ 0 \end{pmatrix} \quad [28]$$

Define Γ , the argument of latitude, to be the angle, measured in the orbital plane, from the ascending node to the satellite as in eqn [29], where θ is the true anomaly and ω is the argument of perigee.

$$\Gamma = \theta + \omega \quad [29]$$

Rotate this vector about the z -axis through the argument of latitude. Rotate again about the x -axis through the inclination angle. Finally, rotate about the z -axis through an angle equal to the right ascension of the satellite less the right ascension of Greenwich. Equations [23a], [23b] and [23c] now yield r_s , latitude φ_s , and longitude λ_s . This method is useful for the navigation problem discussed below.

A second way to streamline these equations is to combine them, which results in eqns [30a], [30b] and [30c].

$$r_s = r \quad [30a]$$

$$\varphi_s = \delta_s = \sin^{-1}(\sin \Gamma \sin i) \quad [30b]$$

$$\begin{aligned} \lambda_s &= \tan^{-1} \left(\frac{\sin \Gamma \cos i}{\cos \Gamma} \right) + \Omega_0 - \Omega_e(t_0) \\ &\quad - \left(\frac{d\Omega_e}{dt} - \frac{d\Omega}{dt} \right) (t - t_0) \end{aligned} \quad [30c]$$

Here r_s is the distance of the satellite calculated with eqn [8]; φ_s and λ_s are its latitude and longitude, respectively. $\Omega_e(t_0)$ is the right ascension of Greenwich at the epoch time, and therefore, $\Omega_0 - \Omega_e(t_0)$ is the longitude of ascending node at the epoch time. The quantity $(d\Omega_e/dt - d\Omega/dt)$ is the relative Earth rotation rate, that is, the rotation rate of the Earth relative to the orbital plane.

Tracking

A list of time versus position of a celestial body is called an 'ephemeris' (plural: ephemerides). To track a satellite, one must be able to point one's antenna at it. The elevation angle, measured from the local horizontal, and the azimuth angle, measured clockwise from the north, can be calculated from the ephemeris data as follows.

Suppose the subsatellite point is at latitude φ_S and longitude λ_S , and that the satellite is at radius r_S from the center of the Earth. Suppose also that the antenna is located at latitude φ_e , longitude λ_e , and radius r_e (the radius of the earth). The Cartesian coordinates of the satellite are then given by eqn [31].

$$\mathbf{r}_S = \begin{pmatrix} x_S \\ y_S \\ z_S \end{pmatrix} = \begin{pmatrix} r_S \cos \varphi_S \cos \lambda_S \\ r_S \cos \varphi_S \sin \lambda_S \\ r_S \sin \varphi_S \end{pmatrix} \quad [31]$$

The Cartesian coordinates of the antenna are given by eqn [32].

$$\mathbf{r}_e = \begin{pmatrix} x_e \\ y_e \\ z_e \end{pmatrix} = \begin{pmatrix} r_e \cos \varphi_e \cos \lambda_e \\ r_e \cos \varphi_e \sin \lambda_e \\ r_e \sin \varphi_e \end{pmatrix} \quad [32]$$

The difference vector $\mathbf{r}_D \equiv \mathbf{r}_S - \mathbf{r}_e$ points from the antenna to the satellite (Figure 14). Assuming a spherical earth, the vector $\mathbf{r}_e$ points to the local vertical (Figure 15). The cosine of the satellite's zenith angle ζ (the complement of the elevation angle) is given by eqn [33].

$$\cos \zeta = \frac{\mathbf{r}_e \cdot \mathbf{r}_D}{|\mathbf{r}_e| |\mathbf{r}_D|} \quad [33]$$

Finding the azimuth angle is a little more difficult. First, we need to find two vectors in the tangent plane at the antenna. The first points north (eqn [34]).

$$\mathbf{r}_N = \begin{pmatrix} x_N \\ y_N \\ z_N \end{pmatrix} = \begin{pmatrix} -\sin \varphi_N \cos \lambda_N \\ -\sin \varphi_N \sin \lambda_N \\ \cos \varphi_N \end{pmatrix}. \quad [34]$$

Figure 14 Satellite tracking geometry.

Figure 15 Definition of zenith angle (ζ) and azimuth angle (ψ).

The second is the horizontal projection of $\mathbf{r}_D$. We define unit vectors in the directions of $\mathbf{r}_e$ and $\mathbf{r}_D$ as in eqns [35a] and [35b].

$$\hat{\mathbf{r}}_e \equiv \frac{\mathbf{r}_e}{|\mathbf{r}_e|} \quad [35a]$$

$$\hat{\mathbf{r}}_D \equiv \frac{\mathbf{r}_D}{|\mathbf{r}_D|} \quad [35b]$$

The required horizontal vector is given by eqn [36].

$$\begin{aligned} \mathbf{r}_H &= \mathbf{r}_D - (\hat{\mathbf{r}}_e \cdot \mathbf{r}_D) \hat{\mathbf{r}}_e = \mathbf{r}_D - |\mathbf{r}_D| \cos \zeta \hat{\mathbf{r}}_e \\ &= |\mathbf{r}_D| (\hat{\mathbf{r}}_D - \cos \zeta \hat{\mathbf{r}}_e) \end{aligned} \quad [36]$$

The azimuth angle ψ is then given by eqn [37].

$$\cos \psi = \frac{\mathbf{r}_N \cdot \mathbf{r}_H}{|\mathbf{r}_N| |\mathbf{r}_H|} \quad [37]$$

One must be careful when taking the inverse cosine. If the satellite is west of the antenna, ψ will be greater than 180° . It must also be noted that these equations assume a spherical Earth. Fortunately, most receiving antennas are insensitive to the slight errors that this assumption causes.

Navigation

In addition to knowing where a satellite is in its orbit, it is necessary to know the Earth coordinates (latitude, longitude) of the particular scene it is viewing. The problem of calculating the Earth coordinates is known as the navigation problem; fundamentally, it is a complex geometry problem. It requires an accurate knowledge of where the satellite is in its orbit, the orientation of the satellite (its attitude), and the scanning geometry of the instrument involved.

Suppose that at a particular time a satellite is at position (x_s, y_s, z_s) with respect to the center of the Earth in the right ascension–declination coordinate system. Suppose further, that the telescope is pointing in a direction specified by declination δ_t and right ascension Ω_t . A unit vector in the direction in which the telescope is pointing is given by eqn [38].

$$\begin{pmatrix} x_T \\ y_T \\ z_T \end{pmatrix} = \begin{pmatrix} \cos \delta_T \cos \Omega_T \\ \cos \delta_T \sin \Omega_T \\ \sin \delta_T \end{pmatrix} \quad [38]$$

Figure 16 shows that the ray from which the telescope receives radiation (that is, the line in space through the

Figure 16 Navigation geometry.

satellite and in the direction of the telescope) is given by eqn [39],

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} x_s + sx_T \\ y_s + sy_T \\ z_s + sz_T \end{pmatrix} \quad [39]$$

where s is the distance from the satellite.

The location at which this ray strikes the spherical Earth is the solution of eqn [40].

$$(x_s + sx_T)^2 + (y_s + sy_T)^2 + (z_s + sz_T)^2 = r_e^2 \quad [40]$$

This is a quadratic equation in s that has no real roots if the ray does not intersect the Earth or two real roots if it does. The smaller root is to be chosen; the larger root represents the location from which the ray re-emerges from the opposite side of the Earth. When the ray is just tangent to the Earth, the two roots are equal. After a solution for s has been found, eqn [39] gives the Cartesian coordinates in the right ascension–declination coordinate system of the point on the Earth's surface being viewed.

One way to specify the telescope pointing vector is to use the pitch, roll, and yaw angles familiar from aircraft flight. Position the satellite on the positive x -axis at distance r_s from the center of the Earth. Let the satellite be traveling in the x - y plane with the positive z -axis on the left; that is, the satellite is traveling eastward in the equatorial plane. Orient the satellite so that its 'nose' is pointing in the $\hat{y}$ -direction (not parallel to the velocity vector), the left 'wing' is pointing in the $\hat{z}$ -direction, and 'up' is in the $\hat{x}$ -direction. Let the telescope begin by pointing straight down toward the center of the Earth, that is in the direction given by eqn [41].

$$\begin{pmatrix} x_T \\ y_T \\ z_T \end{pmatrix} = \begin{pmatrix} -1 \\ 0 \\ 0 \end{pmatrix} \quad [41]$$

Pitch is defined as the angle of rotation about the z -axis; positive is in the sense of the nose pointing up.³ The matrix that accomplishes this rotation is given in eqn [42].

$$\text{Pitch rotation matrix} = \begin{pmatrix} \cos P & -\sin P & 0 \\ \sin P & \cos P & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad [42]$$

A positive pitch angle causes the telescope to point in the along-track direction ahead of the subsatellite point.

Roll is defined as the angle of rotation about the y -axis; positive is in the sense of the left wing pointing up. The matrix that accomplishes this rotation is given in eqn [43].

$$\text{Roll rotation matrix} = \begin{pmatrix} \cos R & 0 & -\sin R \\ 0 & 1 & 0 \\ \sin R & 0 & \cos R \end{pmatrix} \quad [43]$$

A positive roll angle causes the telescope to point in the cross-track direction, to the left of the subsatellite point.

Yaw is defined as the angle of rotation about the x -axis; positive is in the sense of the nose pointing right. The matrix that accomplishes this rotation is given in eqn [44].

$$\text{Yaw rotation matrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos Y & -\sin Y \\ 0 & \sin Y & \cos Y \end{pmatrix} \quad [44]$$

A nonzero yaw angle does nothing to a telescope pointing straight down; however, if the pitch or roll angles are nonzero, a positive yaw angle moves the telescope in a clockwise direction around the subsatellite point.

Common scanning schemes can easily be described with these angles. A cross-track scanner can be described by a roll angle that increases linearly in time (right-to-left scanning) or decreases linearly in time (left-to-right scanning). A conical scanning instrument can be described by a constant pitch angle followed by a yaw angle that increases linearly in time (for clockwise scanning). Finally, a geostationary scanner can be described by a stepped roll angle followed by a pitch angle that increases (west-to-east scanning) or decreases (east-to-west scanning) with time. Corrections in the pitch, roll, and yaw angles need to be applied if the satellite is not aligned as indicated above.

After the appropriate pitch, roll, and yaw rotations have been applied to the initial telescope pointing vector (eqn [41]), eqn [40] yields the distance to the point being observed, and eqn [39] yields the coordinates of the point in the right ascension–declination coordinate system. Now, both the observed point and the satellite can be positioned by (1) rotating the vectors about the z -axis through the argument of latitude, (2) rotating about the x -axis through the inclination angle, and (3) rotating about the z -axis through the right ascension of ascending node less the right ascension of Greenwich. Equations [23a], [23b] and [23c] yield the latitude and longitude of the point. Finally, corrections may need to be applied for the nonspherical Earth and for the height of the terrain or the object being observed.

³ Note that the axes of rotation described here are dependent on the satellite being at the specified position and orientation in the right ascension–declination coordinate system.

The inverse problem, that of finding which satellite datum corresponds to a selected latitude and longitude, is solved iteratively. Each observation has a time associated with it, which determines all of the above angles. First, a time of observation is estimated, and the latitude and longitude of the point being observed at that time are calculated. Then the time is incremented and a new point is calculated. This process is iterated until a satisfactory solution is found.

Space–Time Sampling

To select an orbit for a satellite or a scan pattern for a particular instrument, several questions must be answered: What areas will the orbit and scan pattern allow the instrument to observe? How often will an area be observed? At what local times will the observations be made? At what viewing zenith and azimuth angles will the observations be made? What will be the solar zenith and azimuth angle when the area is being observed? These questions are all aspects of what is called space–time sampling. Using the equations in this article plus some easily acquired equations that describe the position of the Sun, these questions can be answered.

Synopsis

This article explains the fundamental principle and retrieval methodology of measuring precipitation from satellites. Radiative signatures of precipitation are first examined at visible, infrared, and microwave spectra using radiative transfer theory with a real-world example. Techniques developed for precipitation retrievals are then introduced, including those using only a single wave spectrum and those combining multiple wave spectra from multiple satellites. Topics on measuring rainfall by space-borne radars and research on snowfall remote sensing are also introduced in light of the recent advancement in observing precipitation by active and high-frequency microwave sensors.

Introduction

Precipitation is one of the least well-measured atmospheric parameters, especially over the vast oceanic regions on the globe. There are two major obstacles that contribute to the lack of comprehensive global precipitation measurements. First, there are few surface-based observations over the oceanic areas, which cover about two-thirds of the Earth's surface. Second, precipitation is highly variable in both time and space compared to atmospheric variables such as temperature and pressure. Rainfall measured by a rain gauge at a given location can be significantly different from that measured just a couple of hundred meters away; similarly, rainfall measured at a given time can be significantly different from that measured just minutes earlier or later. As a result, a high-density rain gauge network is required in order to reasonably measure rainfall over a given area if one attempts to derive the area rain total from rain gauge observations alone. Such a high-density rain gauge network is generally not available even in well-developed countries and regions. Although ground-based radars can provide better spatial and temporal coverage than rain gauges, well-calibrated radars are available only in limited land regions in developed countries. These limitations related to surface-based measurements make satellite remote sensing indispensable.

Satellite remote sensing of precipitation is based on the radiative intensities emitted or reflected by cloud and precipitating hydrometeors. For infrared and microwave wavelengths, the radiative intensity is often expressed in terms of brightness temperature, defined as the temperature that is required to match the measured intensity to the Planck blackbody function. Brightness temperature in the infrared spectrum often represents the physical temperature of the cloud top because most clouds are optically thick for infrared radiation. Microwave radiation, however, can penetrate through cloud and rain layers, and its intensity reflects the integrated contribution by all water drops and ice particles in the atmospheric column. In the visible spectrum, the measured radiative intensity is due to the reflection of sunlight by the cloud and surface features. The dependence on sunlight limits the utility of visible sensing to daylight hours. Although visible radiation has a deeper penetration than infrared radiation, the visible reflectivity still reflects only the top portion of clouds.

Methods for passive satellite remote sensing of precipitation may be divided into the following three categories, based on

whether the information received by a satellite reflects the physical properties near the cloud top or over the whole atmospheric column: (1) sensing by visible and infrared radiation; (2) sensing by microwave radiation; and (3) sensing by a combination of visible, infrared, and microwave radiations. Visible and infrared methods are physically indirect because precipitation is derived from the radiative properties near the cloud top. In comparison, microwave techniques use more direct information on the vertical distribution of hydrometeors. In this article, the precipitation signatures at different wave spectra are first discussed using an actual satellite observation. The principles of satellite remote sensing under each of the aforementioned categories are then explained, omitting specific details of any particular retrieval algorithm.

Active sensing by space-borne radars is another important development for satellite remote sensing of precipitation in recent years. The basic principle of radar sensing from space is essentially the same as that sensing from ground (i.e., the radar reflectivity–rainfall rate relationship). The topic of measuring precipitation by ground-based radars is covered more thoroughly in other places of this book; the explanation of the measuring methodology given in this article will then be brief. So far, there have been two space-borne radars that are capable measuring precipitation: the Tropical Rainfall Measuring Mission's Precipitation Radar instrument and CloudSat's Cloud Profiling Radar. The former was designed to measure rainfall in the tropics, and the latter, while designed for measuring cloud water, is also suitable to measure light precipitation and snowfall.

The Radiative Signatures of Precipitation

The radiative signatures of precipitation may be understood by examining the observations of a hurricane shown in **Figures 1 and 2**, which display data simultaneously collected by a number of sensors on the Tropical Rainfall Measuring Mission's satellite. **Figure 1** is a thermal infrared image over the southeastern Pacific Ocean. The image covers an area approximately 720 km wide by 3050 km long. **Figure 2** shows the observed radiative properties at the satellite nadir along line A–B (see **Figure 1**), which crosses the outer cloud band of the hurricane. The parameters shown in **Figure 2** include a space radar-derived rainfall rate cross-section, near-surface

Figure 1 Thermal infrared image of a hurricane over the southeastern Pacific Ocean observed by an infrared radiometer on a Tropical Rainfall Measuring Mission satellite. The image covers an area approximately 720 km wide by 3050 km long on 5 January 1998.

rain (also derived from the space radar; because of surface contamination for space radar measurements under 1 km, the mean rainfall rate between 1 and 2 km above sea level is used here), visible reflectivity at $0.63 \mu\text{m}$, and brightness temperatures at infrared ($11 \mu\text{m}$) and microwave (19 and 85 GHz, horizontal polarization) wavelengths. The radar data indicate that the major rainfall area is on the right side in Figure 2, which corresponds to the deep clouds to the right of the hurricane's eye. Compared to those in the cloud-free area near point B, radiometric properties for the rainy areas show the following features: high visible reflectivities, low infrared brightness temperatures, high brightness temperatures at 19 GHz, and low brightness temperatures at 85 GHz. Most of the areas covered by the spiral cloud are actually not associated with rain, although clouds in those areas have low infrared brightness temperature and high visible reflectivity. It is the microwave brightness temperatures that most closely follow the radar-observed rainfall variation. The radiative properties shown here comprise the fundamental basis for satellite remote sensing of precipitation. They are explained theoretically in this section.

Radiative Transfer Equation

The radiative energy received by a satellite radiometer is either emitted (terrestrial radiation) or reflected (solar radiation) by the Earth-atmosphere system. Over 99% of the solar

Figure 2 Radiative properties of hurricane clouds along line A–B shown in Figure 1, including a distance–height cross-section of the rainfall rate from radar, near-surface rainfall rate, visible reflectivity, and brightness temperatures at $11 \mu\text{m}$ (infrared) and 19 and 85 GHz (microwave).

(terrestrial) radiative energy is distributed in the spectra with wavelengths shorter (longer) than $4 \mu\text{m}$. Therefore, it is common that solar and terrestrial radiations are treated separately in radiative transfer models. For a plane-parallel atmosphere, the radiative transfer equation at a given wavelength can be expressed by eqn [1].

$$\mu \frac{dI(\tau, \mu)}{d\tau} = I(\tau, \mu) - \frac{\omega_0}{2} \int_{-1}^{+1} I(\tau, \mu') P(\mu, \mu') d\mu' - J(\tau) \quad [1]$$

In eqn [1], $J(\tau) = (1 - \omega_0)B(\tau)$ for terrestrial radiation, $J(\tau) = \frac{\omega_0}{4\pi} F_0 e^{-\tau/\mu_0} P(\mu, \mu_0)$ for solar radiation, τ is optical depth defined to be zero at the top of the atmosphere and increases with lowering altitude, μ and μ' are the cosine of the emergent and incident zenith angles of the wave, $I(\tau, \mu)$ denotes the radiance at optical depth level τ and emergent direction μ , ω_0 is the single-scatter albedo defined by the ratio of the scattering to extinction coefficients, μ_0 is the cosine of the solar zenith angle, P is the scattering phase function describing the angular distribution of scattered radiation, F_0 is the solar flux at the top of the atmosphere, and $B(\tau)$ is the Planck's function at

optical depth τ . Satellite-received radiances may be understood by solving radiative transfer equation [1].

Visible Reflectivity

In the visible spectrum, reflectivity increases with cloud optical depth, which is approximately proportional to liquid water path (vertically integrated liquid water) if the effective particle size remains constant. Therefore, clouds with higher values of liquid water path are more reflective. Generally, these clouds are also more likely to be associated with precipitation. This is the underlying principle for sensing precipitation by visible reflectivity. However, the sensitivity of visible reflectivity to liquid water path decreases with the increase of optical depth, and becomes virtually insensitive when optical depth is larger than 100, a value that a precipitating cloud easily exceeds. Consequently, instead of sensing the entire vertical column, reflected radiation at a visible wavelength represents the microphysical properties only near the top portion of a cloud. Therefore, the relation between the visible reflectivity and the rainfall rate at the surface is rather indirect.

Infrared Brightness Temperature

Cloud droplets are very absorptive in the thermal infrared spectrum. A consequence of this high absorption is that the cloud top may be viewed as the surface of a blackbody having a temperature the same as the air temperature at the level of the cloud top. Therefore, the infrared brightness temperature indicates the cloud top temperature except for in the case of optically thin cirrus clouds. At least in the tropics, most rainfalls are associated with well-developed convective systems that have tall cloud tops. Statistically, colder infrared brightness temperatures often indicate higher rainfall rates at the surface. However, shallow convections with warm cloud tops do sometimes produce substantial rainfall. On the other hand, nonprecipitating cirrus clouds do not produce rainfall, although they also have cold cloud top temperatures. Problems associated with the infrared sensing of rainfall are more serious in the midlatitudes, where most precipitation is produced by frontal stratiform clouds, for which cloud top temperature and precipitation are less correlated than for deep tropical convections.

Microwave Brightness Temperature

Microwave radiation received by satellite sensors measures the integrated radiative effects by the surface, atmospheric gases, and hydrometeors. Microwave brightness temperatures may either increase or decrease with increasing rainfall rate, depending on the frequency and the cloud microphysical properties. To understand the microwave signatures, consider an idealized rain cloud that contains raindrops below freezing level and ice particles above. Although accurate estimation of satellite-received radiation requires solving a radiative transfer model (eqn [1]) with absorption and multiple scattering, the primary radiative signature may be understood by examining the following approximation in eqn [2].

$$T_B \approx T_s [1 - e^{-2\tau_w} (1 - \varepsilon_s)] e^{-\tau_i} \quad [2]$$

In eqn [2], T_B is the brightness temperature received by the satellite; T_s is the surface temperature; τ_w and τ_i are the optical depths for the raindrops and ice particles, respectively; and ε_s is the surface emissivity. Note that radiance is proportional to brightness temperature at the microwave spectrum according to the Rayleigh-Jeans approximation. Therefore, brightness temperature T_B is used in eqn [2] to replace radiance I in eqn [1]. For simplicity, emission from atmospheric gases is not included in this equation, although its contribution is important, particularly near water vapor and oxygen-absorbing frequencies (e.g., 22 and 60 GHz). The emissivities for land and water surface are roughly 1 and 0.5, respectively, for microwave frequencies commonly used for precipitation retrievals. Consider the two situations given in the 'Low-frequency (<20 GHz) microwave radiation' and 'High-frequency (>80 GHz) microwave radiation' subsections.

Low-frequency (<20 GHz) microwave radiation

If the frequency is sufficient low, scattering by ice particles aloft becomes negligible (i.e., $\tau_i \approx 0$). Equation [2] then becomes eqn [3].

$$\begin{aligned} T_B &\approx T_s && \text{over land} \\ T_B &\approx T_s [1 - e^{-2\tau_w} (1 - \varepsilon_s)] && \text{over ocean} \end{aligned} \quad [3]$$

It is seen that rainfall cannot be detected over land by low-frequency microwaves because of the high surface emissivity. Since ocean surface temperature and emissivity generally do not vary dramatically, the small spatial or short temporal-scale variation of brightness temperature in eqn [3] can be attributed to the change in optical depth of raindrops, τ_w , which is approximately proportional to integrated total rainwater amount. Because total rainwater is closely related to the surface rain, low-frequency microwave brightness temperature over the ocean provides a relatively direct representation of rainfall rate. This positive correlation between rainfall rate and brightness temperature is shown in Figure 2 for 19 GHz. Because the increase of brightness temperature is due to the emission by raindrops, the rainfall signature in low microwave frequencies is called an emission signature. Figure 3 depicts brightness temperatures calculated by a radiative transfer model for nadir viewing at 19 GHz for various assumed freezing level heights. Brightness temperature increases with rainfall rate until reaching a maximum that indicates the saturation of microwave radiation. If rainfall rate further increases beyond the saturation point, the brightness temperature starts to decrease. The saturation problem prevents higher rainfall rates from being retrieved using microwave emission signatures.

High-frequency (>80 GHz) microwave radiation

For high-frequency microwaves, scattering by ice particles aloft is no longer negligible; rather, it becomes the dominant signature of the rain cloud. The optical depth due to raindrops, τ_w , usually is so large at high frequencies that $e^{-2\tau_w} \approx 0$. Equation [2] then becomes eqn [4].

$$T_B \approx T_s e^{-\tau_i} \quad [4]$$

Brightness temperature decreases with increasing optical depth of ice particles. The low value of the imaginary part of the ice dielectric constant determines that scattering is the dominant process for the interaction between ice particles and

Figure 3 Brightness temperature for nadir viewing over an ocean surface at 19 GHz for various assumed freezing levels calculated by a radiative transfer model. American Meteorological Society, Boston, pp. 1226–1232.

microwave radiation. Since a scattering cross-section is approximately proportional to the sixth power of the particle diameter, large and dense ice particles contribute the most to τ_i . Therefore, lower brightness temperatures at high microwave frequencies indicate more large ice particles aloft, which is commonly an indication of heavier rainfall rates at the surface. This relation is seen in [Figure 2](#) for 85 GHz microwave observations. Since the decrease of brightness temperature is caused by ice scattering, the rainfall signature at high microwave frequencies is called the scattering signature. Compared to the microwave emission signature, the scattering signature is a relatively indirect indication of surface rainfall. In [Figure 4](#), the model-simulated brightness temperatures at 92 GHz are shown for a 45° viewing angle. The brightness temperature falls more than 100 K for a rainfall rate increasing from 1 to 15 mm h⁻¹ given a 1 km ice layer. It must be cautioned that the magnitude of the brightness temperature depression due to ice scattering depends greatly upon ice particle size, shape, and density, for which there have not been sufficient observations available so far.

Sensing by Visible and Infrared Measurements

Since visible reflectivity and infrared brightness temperature are physically indirect indicators of surface rainfall, satellite retrieval techniques based on visible and infrared measurements are generally based on regression. That is, surface rainfall data, measured by rain gauges, radars, or both, are considered to be true values; colocated satellite-measured radiative properties are regressed against the true values to derive a statistical expression relating surface rainfall to satellite measurements. The true rainfall data are usually available for only limited regions and periods. As a result, most of these algorithms are subject to significant errors in regions where the climatological conditions are different. In addition, because of the statistical nature of these algorithms, retrieval accuracy generally increases with the increase of averaging area and time.

Figure 4 Brightness temperature calculations at 92 GHz (horizontal polarization, 45° view angle) for various thicknesses of the ice layer as a function of rainfall rate (lower abscissa). The two upper abscissae give the mean particle radius and the particle density corresponding to the rainfall rate through Marshall–Palmer size distribution. Adapted with permission from Wilheit, T.T., 1986. Some comments on passive microwave measurement of rain. In: *Bulletin of the American Meteorological Society*, vol. 67. American Meteorological Society, Boston, pp. 1226–1232.

Simple Regression

The notion that colder cloud tops usually correspond to heavier rainfall leads to the most straightforward approach: simply regressing rainfall rate against infrared radiation. This type of approach has mostly been done using broadband outgoing longwave radiation, instead of narrow-band brightness temperature within the atmospheric window (8–12 μm). A variety of equations relating rainfall rate to outgoing longwave radiation have been derived. Nonlinear functions are commonly used to account for the nonlinearity of the relation between the two parameters.

Area Time Integral Techniques

Studies of surface radar and rain gauge observations have shown that the total volume of rain falling over a sufficiently large area and for a long enough time period can be well predicted by the so-called area time integral (ATI) (eqn [5]).

$$ATI = \int A(X > X_{th}) dt \quad [5]$$

where X is the measured radiative property, $A(X > X_{th})$ is the area with X exceeding a threshold X_{th} , and the integration is over time t . The most utilized, infrared algorithm that uses this

principle is the GOES Precipitation Index (GPI), which gives the rain total over an area of 2.5° latitude by 2.5° longitude and for a time period of Δt (eqn [6]).

$$\text{GPI} = R_0 A (T_B < T_{B0}) \Delta t \quad [6]$$

$R_0 = 3 \text{ mm h}^{-1}$ and $T_{B0} = 235 \text{ K}$ are determined by comparing satellite measurements with ground radar observations over the tropical Atlantic Ocean. In essence, eqn [6] states that only the clouds with top temperatures colder than 235 K produce rain, and their average rainfall rate is 3 mm h^{-1} . This algorithm works reasonably well within the tropical belt of $30^\circ \text{ S} - 0^\circ \text{ N}$ for the monthly rain total. Errors increase dramatically toward high latitudes, particularly during cold seasons.

A number of other techniques have been similarly developed, but they take into account rain types and storm development stages. It is well established that deep convection more often produces heavy rainfall than stratiform clouds. The most common technique for determining cloud types relies on horizontal texture information of satellite images, such as identifying a local minimum in infrared brightness temperature imagery as the convective center and the surrounding relatively smooth portion as stratiform. If we divide observations over an area into several types, the rain total may be expressed by eqn [7], where R_i is the average rainfall rate for type i , which covers an area fraction of A_i and a time duration of Δt_i .

$$R = \sum_i R_i A_i \Delta t_i \quad [7]$$

This method is known as the 'cloud indexing' technique.

Observations also show that for thunderstorms, the rainfall rate peaks while its cloud area is growing rapidly, and rainfall is much reduced at the time of maximum cloud area. In techniques that include cloud life history, a different average rainfall rate R_i will be assigned for different development stages. This method is known as the 'life-history' technique.

Bispectral Techniques

Both infrared and visible measurements have important deficiencies in detecting rainfall. For example, stratus clouds are highly reflective but do not rain as much, or as often, as cumulonimbus clouds. Also, cirrus cloud tops are cold but do not produce rainfall. Bispectral techniques seek to combine information from visible and infrared measurements to obtain the optimal rainfall retrieval. In one such method, two lookup tables are first generated using coincident satellite and ground truth data. One of the tables is the probability of rain p_{ij} , determined by the ratio of raining cases to all cases in the infrared brightness temperature bin i and visible reflectivity bin j . Another table gives the mean rainfall rate r_{ij} , derived only from raining cases in the same two-dimensional bin. The variation of the rain possibility and mean rainfall rate in the reflectivity–brightness temperature space are schematically shown in Figure 5. For a given pixel whose brightness temperature falls in the i th and whose reflectivity falls in the j th bin, rainfall rate may be determined by eqn [8].

$$R = p_{ij} r_{ij} \quad [8]$$

Most bispectral methods attempt to retrieve instantaneous rainfall rate by constantly updating the lookup tables using

Figure 5 Schematic illustration of the probability of rain (p) and mean rainfall rate (r) in a two-dimensional diagram of visible reflectivity and infrared brightness temperature. dp and dr are positive increments.

radar, rain gauge, or even satellite microwave observations as truth. At least in theory, the bispectral methods should be superior to infrared-only or visible-only methods. However, this superiority has not been convincingly demonstrated, partially because visible data are available for only a fraction of the day, and partially because many other uncertainties still remain, such as the quality of truth data and the collocation of satellite and surface data.

Sensing by Microwave Measurements

Owing to its physical directness, microwave sensing of precipitation has received particular attention since the late 1970s. Except for only a few pure regression-type algorithms, a characteristic of the microwave methods is that they rely on radiative transfer models either at the algorithm-developing stage or during the retrieval computation. Through a radiative transfer model, microwave brightness temperatures are directly connected to the amount and distribution of precipitating hydrometeors. The microwave algorithms may be grouped into the categories of emission-based techniques, scattering-based techniques, techniques using both emission and scattering, and techniques based on the a priori radiation–rain database.

Emission-Based Techniques

The emission signature provides the most direct physical relation between rainfall and brightness temperature. Data from frequencies under 20 GHz are primarily used for this type of algorithm, although higher frequencies are sometimes included to minimize atmospheric water vapor and/or surface effects. The relation between brightness temperature and rainfall rate may be derived from radiative transfer model calculations by specifying the atmospheric temperature and humidity profiles, cloud liquid water content, rain layer thickness, and size

distribution of raindrops. The most commonly used raindrop size distribution is the so-called Marshall–Palmer distribution, in which the number concentration decreases exponentially with drop size. Rain layer depth may be assumed to be freezing level height, although the validity of this assumption deserves further investigation. There are several problems associated with emission-based algorithms: (1) They may be applied only over oceans; the high land surface emissivity prevents emission signatures from being detected by a low-frequency microwave radiometer. (2) Brightness temperature saturates for heavy rains. This problem is particularly serious for tropical regions where the rain layer is deep. (3) A nonuniform rainfall rate across the beam causes underestimation of the rainfall rate. As shown in Figure 3, the brightness temperature versus rainfall rate relation is highly nonlinear. The spatial resolution of a satellite pixel for microwave radiometers is on the order of several tens of kilometers; the rain field within one satellite pixel is generally inhomogeneous. If $R = R(T_B)$ is the theoretical relation between brightness temperature T_B and rainfall rate R for a homogeneous rain field, the retrieval resulting from the field-of-view-averaged brightness temperature $R(\bar{T}_B)$ does not equal the field-of-view-averaged rainfall rate $\bar{R}(T_B)$. Instead, in the case of microwave emission, it is always true that $R(\bar{T}_B) < \bar{R}(T_B)$ (i.e., the technique underestimates rain rate).

Scattering-Based Techniques

The scattering signature is physically less directly related to precipitation than the emission signature because it is an indication of the ice amount above freezing level. Frequencies higher than 80 GHz are primarily used for scattering-based algorithms. Algorithms have been developed either based on statistically regressing brightness temperatures to surface rainfall measurements or using results of radiative transfer models. The advantage of scattering-based algorithms is that they can be applied over both ocean and land. However, this type of algorithm has greater errors for regions where warm rains have a significant contribution.

Techniques Using Both Emission and Scattering

For rain associated with a shallow rain layer, scattering-based techniques fail to work because of lack of ice scattering. For heavy rainfall with deep rain layers, emission-based techniques cannot correctly determine rainfall rate because brightness temperature saturates. A better solution is to take advantage of both emission and scattering signatures by combining them in a single algorithm. One such algorithm is a ‘microwave index’ defined for the US Defense Meteorological Satellite Program’s Special Sensor Microwave/Imager according to eqn [9].

$$MWI = (1 - D/D_0) + 2(1 - PCT/PCT_0) \quad [9]$$

Here, $D = T_{B19V} - T_{B19H}$ is the depolarization at 19 GHz, and $PCT = 1.818T_{B85V} - 0.818T_{B85H}$ is the polarization-corrected brightness temperature at 85 GHz. In brightness temperature T_{Bvp} , the subscript v depicts frequency and the subscript p depicts polarization (V for vertical and H for horizontal). D_0 and PCT_0 are the rain threshold values for D and PCT . The first term in eqn [9] is the emission signature, and the second term is the scattering signature. Because D decreases monotonically

with the increase of rainfall rate, it represents the emission signature better than 19 GHz brightness temperatures themselves. Figure 6 depicts the 19 and 85 GHz brightness temperatures and microwave index for a viewing angle of 53° . The results are calculated from a radiative transfer model assuming that a typical tropical profile of hydrometeors for deep convection agreed. The microwave index relates to rainfall rate monotonically without saturation. An alternative way to combine the two signatures is to use the emission signature until brightness temperature at low frequency saturates, then to use the scattering signature at higher rainfall rates.

Techniques Based on the A Priori Radiation–Rain Database

Knowing the surface emissivity and vertical distributions of atmospheric temperature, humidity, and hydrometeors, brightness temperatures at satellite-observing frequencies can be calculated by a radiative transfer model. However, inversely, from brightness temperatures observed at several frequencies, multiple values of surface rainfall rate can be realized since several different combinations of the surface conditions and the atmospheric and hydrometeor distributions may result in the same upwelling radiation emerging from the top of the atmosphere. To solve this nonuniqueness problem in the retrieval, a commonly used technique is to apply a priori knowledge on rain profiles as a constraint, so that the retrieval algorithm searches solutions only within the ‘likely range.’ This technique generally consists of the following retrieval procedures. First, a large database of vertical profiles of hydrometeors and their corresponding brightness temperatures at satellite-observing frequencies must be prepared. The variety and the frequency of occurrence of rain profiles in the database should represent what occur in nature. This database may be prepared using actual observations, numerical cloud and radiative transfer model simulations, or a combination of both. However, because of the lack of observational data, this database has usually been constructed with simulated results from numerical cloud and radiative transfer models. In performing the retrieval, the set of brightness temperatures that most closely matches the satellite observed is selected, and the hydrometeor profiles corresponding to the best match are determined to be the retrieval. The retrieval produces not only rainfall rate at the surface but also its vertical distribution.

One implementation of this technique is based on the Bayes’ theorem, in which the posterior probability density function $p_{\text{post}}(\vec{R}|\vec{T}_B)$ of a rain profile $\vec{R}$ for a given set of measured brightness temperatures $\vec{T}_B$ can be expressed by eqn [10].

$$p_{\text{post}}(\vec{R}|\vec{T}_B) = \frac{p(\vec{T}_B|\vec{R})p_{\text{prior}}(\vec{R})}{\int_{\text{database}} p(\vec{T}_B|\vec{R})p_{\text{prior}}(\vec{R})d\vec{R}} \quad [10]$$

Here, $p_{\text{prior}}(\vec{R})$ is the prior probability density function of rain profile $\vec{R}$, and $p(\vec{T}_B|\vec{R})$ is the conditional probability density function of the set of brightness temperatures $\vec{T}_B$ given the rain profile $\vec{R}$. The integration in the denominator of eqn [10] is done over the database. Commonly, $p(\vec{T}_B|\vec{R})$ is assumed to be a multivariate normally distributed function with its maximum where the brightness temperatures in the database match satellite-observed values, and its standard deviation is proportional to the instrumental and radiative

Figure 6 Radiative transfer model calculated brightness temperatures at 19 and 85 GHz, and microwave index (MWI) over ocean as a function of rainfall rate for tropical convective rains. A viewing of 53° is assumed, and the brightness temperatures shown are for horizontal polarization.

transfer model uncertainties. The posterior probability density function $p_{\text{post}}(\vec{R}|\vec{T}_B)$ gives the likelihood of a rain profile based on the observed brightness temperatures and the a priori knowledge. The retrieved rain profile $\hat{R}$ and its uncertainty σ_R^2 may be expressed by eqns [11] and [12], respectively.

$$\hat{R} = \int_{\text{database}} \vec{R} p_{\text{post}}(\vec{R}|\vec{T}_B) d\vec{R} \quad [11]$$

$$\sigma_R^2 = \int_{\text{database}} (\vec{R} - \hat{R})^2 p_{\text{post}}(\vec{R}|\vec{T}_B) d\vec{R} \quad [12]$$

The a priori database-based techniques have the advantage of fully using physical relations between cloud microphysics and microwave radiation. With more observational data becoming available in the future to build the database of hydrometeor profiles, this approach is expected to play a more significant role in satellite remote sensing of precipitation.

Combination of Multichannel and Multiplatforms

Currently, it is practical to put microwave radiometers only on low-altitude polar-orbiting satellites to ensure useful spatial resolution. The frequency of observation by a single satellite at

a certain area on Earth is unacceptably low (1–2 times a day) for determining rainfall accumulation. As a result, although microwave techniques work better for instantaneous rainfall rate retrieval, they do not outperform visible and infrared techniques on daily or monthly time scales, because visible and infrared measurements are more frequent. Therefore, combining measurements from multiple wave bands and multiple platforms has been proposed. One proposed approach is to increase the number of satellites that carry microwave sensors, so that local sampling frequency will be increased to an acceptable level. With increasing international collaboration, this proposal is expected to become reality in the near future, such as with the Global Precipitation Measurement project. The current solution has been to combine visible, infrared, and microwave measurements from available satellites. Visible and infrared measurements have the advantage of ample coverage, while microwave measurements have the advantage of physical directness. The combined techniques use microwave retrievals as truth to constantly train visible and infrared algorithms, while the trained visible and infrared algorithms are used to fill the gap left by microwave measurements. Figure 7 shows the global distribution and the zonally averaged values of rainfall rate derived by the Global Precipitation Climatology Project using 30 years (1979–2008) of multichannel multisatellite data (surface rain gauge data are also included). High rainfall rates

Figure 7 Global rain map (left) and its zonal distribution (right) derived from 30 years (1979–2008) of Global Precipitation Climatology Project (GPCP) data.

are observed in the intertropical convergence zone and along the midlatitude storm tracks. The zonal mean rainfall rate in the intertropical convergence zone is about 6 mm day^{-1} , or over 2 m rain total for a year. The secondary maxima of the zonal mean rainfall rate occur in the midlatitudes in both hemispheres, with a magnitude of about half of that in the intertropical convergence zone.

Sensing by Space-Borne Radars

Active remote sensing by space-borne radars provides the three-dimensional structure of precipitation. Tropical Rainfall Measuring Mission Precipitation Radar, operating at 13.8 GHz ($\sim 2.2 \text{ cm}$ wavelength), is the first precipitation radar instrument onboard a satellite. An example of this radar's observation of hurricane rainfall has been shown in Figure 2.

In contrast to radiometers that passively receive energy emitted or reflected by the Earth's surface and atmospheric constituents, radars actively transmit radiative energy, then receive the portion of energy scattered back. The backscattering intensity is represented by radar reflectivity factor Z , as defined by eqn [13].

$$Z = \frac{\lambda^4}{\pi^5 |K|^2} \int_0^\infty n(D) \sigma_b(D) dD \quad [13]$$

Here, λ is wavelength, K is a parameter determined by the refractive index of the scattering particles, $n(D)$ is the particle size distribution, and $\sigma_b(D)$ is the backscattering cross-section of particle diameter D . If the particle diameter is much smaller than the wavelength (Rayleigh-scattering regime), the backscattering cross-section will be proportional to D^6 , and radar reflectivity factor Z may be simplified to eqn [14].

$$Z = \int_0^\infty n(D) D^6 dD \quad [14]$$

Rainfall rate R , on the other hand, is the water volume flux defined by eqn [15].

$$R = \frac{\pi}{6} \int_0^\infty n(D) D^3 v(D) dD \quad [15]$$

$v(D)$ is the terminal velocity and is approximately related to drop size by $D^{0.5}$ for water drops. Comparing eqns [14] and [15], it is found that Z and R are approximately the sixth and 3.5th moment of the particle size distribution, respectively. Therefore, the Z - R relationship is not fixed but varies with the particle size distribution, which is the major factor contributing to the uncertainty in radar-derived rainfall rate. In order to reduce the uncertainty, dual-wavelength radar measurements have been designed for future Global Precipitation Measurement missions, in which at least one of the radar wavelengths must be short enough not to be in the Rayleigh-scattering regime, so that its radar reflectivity factor does not follow the relation given in eqn [14]. Two pieces of information can be obtained by the dual-wavelength radar measurements: the amount of rainwater and the mean size of raindrops. Rainfall rate retrieval algorithms can then be better constrained by using both the rainwater amount and drop size information.

Satellite Remote Sensing of Snowfall

At high latitudes during cold seasons, precipitation often takes the form of snowfall, which generally is more difficult to retrieve from satellite observations. A number of factors contribute to these difficulties. First, due to their low density, scattering by snowflakes is usually weak, which hampers snowfall detectability by both radars and radiometers. Second, for passive microwave observations, the scattering signal due to snow accumulation on ground is hardly distinguishable from that of falling snow. Third, unlike water drops, snowflakes are nonspherical; their scattering properties have not been well understood.

Figure 8 Snowfall maps derived from 4.5 years (June 2006–December 2010) of CloudSat radar data. Top: 30° N–90° N; bottom: 30° S–90° S.

Active and passive techniques for satellite remote sensing of snowfall have been developed using current microwave observations, although both techniques are still in their infancy. High-frequency microwave observations from 89 to 183 GHz have been used in the passive sensing technique. Similar to retrieving rainfall over land, the reduction of upwelling brightness temperature due to ice scattering is the primary signature for snowfall rate retrieval. An active technique for sensing snowfall has been developed using CloudSat's Cloud Profiling Radar data. This radar operates at 94 GHz (3.2 mm wavelength) and has a minimum detectable

radar reflectivity of -26 dBZ. It was originally designed for measuring liquid and ice water content in clouds. However, the low attenuation due to snowflakes together with the radar's high detectability make it suitable for measuring snowfall as well. A snowfall map derived from 4.5 years (June 2006–December 2010) of CloudSat data is shown in [Figure 8](#). In deriving this map, radar reflectivity data at 1 km above the surface have been used since data below 1 km altitude are often contaminated by surface returns. The snowfall map displays the following features. In the Southern Hemisphere, there is an almost zonally orientated high snowfall zone centered at approximately 65° S. In the Northern Hemisphere, however, heavy snowfall is mostly locked to geographical locations related to storm tracks. Additionally, the zonally averaged snowfall rate reaches about 2 mm day^{-1} , which is about one-third of the zonally averaged rainfall values found in the tropics, signifying the importance of snowfall in the hydrological cycle.

Synopsis

Clouds constitute a unique and important component of the atmosphere. This article briefly reviews the methods of inferring cloud-top height, determining cloud thermodynamic phase, and retrieving cloud microphysical and optical properties (specifically, the effective particle size and optical thickness). Some examples based on observations made by a passive spaceborne sensor (the Moderate Resolution Imaging Spectroradiometer) and an active spaceborne sensor (the Cloud–Aerosol Lidar with Orthogonal Polarization) are illustrated.

Introduction

On any given day, clouds cover about 65% of the planet. In a fairly stable atmosphere, clouds may be cellular in appearance (i.e., cumuliform) or may appear in sheets (i.e., stratiform) that may extend over large horizontal distances. While these clouds may extend over wide areas, their typical geometric thickness is less than 1 km. In unstable atmospheres, clouds may extend from near the planet's surface to the upper troposphere. As most of the tropospheric water vapor resides near the surface, where temperatures tend to be relatively warm, low-level clouds tend to be composed of water droplets and are generally opaque to the viewer. The opacity is denoted in terms of a quantity known as optical thickness, or optical depth, and is a dimensionless measure of light attenuation caused by the scattering and absorption of energy by atmospheric particles. Clouds forming near the tropopause reside at very cold temperatures and are typically composed of ice particles. For clouds at intermediate heights between the planetary boundary layer (~ 1 km above the surface) and the middle troposphere, clouds may be composed of a mixture of supercooled water and ice particles. Water and ice clouds interact with solar radiation differently and have a large influence on the Earth's radiative energy budget. The energy budget is composed of both solar and terrestrial radiation components. Solar radiation spans from ultraviolet ($\lambda < 0.4$ μm , where λ is the wavelength) to infrared (IR) wavelengths ($\lambda > 5$ μm). A portion of the incoming solar radiation may be absorbed at the surface and within the atmosphere by clouds, aerosols, water vapor, and other trace gases such as carbon dioxide and methane. Subsequently, absorbed solar radiation is reemitted at longer wavelengths ranging from 5 to 100 μm .

Data from operational polar-orbiting and geostationary meteorological satellites are analyzed routinely for global cloud macrophysical properties such as cloud height, phase (water, ice, or some mixture of both), and microphysical and optical properties such as optical thickness and the effective particle size. Global cloud observations based on satellite measurements serve many uses. In numerical weather models, where the time scale of interest is on the order of hours to days, satellite-derived cloud and clear-sky properties from the geostationary satellites can serve as initial conditions for the models, that is, where the clouds are at some given time, their

height, and other properties. Numerical weather models may be regional in extent, covering a specific area such as North America, or global, in which case global and near real-time clouds and clear-sky properties are required for initialization of the models. Monthly, annual, or decadal averages of satellite-derived cloud properties are also useful for comparing with results from global climate models where the time scale of interest is much longer than for weather prediction models. For this type of use, cloud properties need to be collected, analyzed, and ultimately reduced to a global-gridded and time-interpolated product. An example of such a product would be one where each of the cloud properties retrieved during the course of a month is reduced to a monthly average with a time resolution of every 3–6 h. One of the primary issues in building a decadal climatology based on satellite observations is that the satellite sensor calibration needs to be very accurate. Since the advent of meteorological satellites, beginning around 1980, a long line of weather satellites have come into or out of service. Once in space, the platforms are subject to very harsh environments that can modify the sensor calibration over time, and for polar-orbiting platforms, the orbit can degrade over time. The derivation of a decadal record of cloud properties requires constant attention to sensor calibration.

To date, meteorological satellites have recorded information over the Earth at a limited number of wavelengths through the use of specially designed filter radiometers. The filters only allow radiation over a very narrow wavelength range to pass through to the detectors. Such narrowband wavelengths are typically chosen in atmospheric 'windows,' where the atmospheric constituents such as water vapor and carbon dioxide least attenuate the energy along the path to/from the surface, through the atmosphere, and finally to the satellite. At a minimum, operational satellite data are recorded at a visible (VIS) wavelength (e.g., 0.65 μm), a medium-wave-infrared (MWIR) wavelength (3.82 μm), and an IR wavelength (11 μm). Radiances at VIS and near-IR wavelengths are often converted to reflectances whose values range from 0 to 1. IR radiances are often converted to brightness temperatures (BTs) through application of the Planck function. Because of the huge volumes of data collected by satellites, the data reduction effort can become quite complex. In this article, we will discuss some of the available methods to infer cloud properties such as

cloud-top pressure, phase, optical thickness, and the effective particle size.

Cloud-Top Pressure–Height–Temperature

Over the past several decades, a number of approaches have been developed to infer cloud-top heights from satellite multispectral data. Actually, the literature provides a wealth of different research-grade algorithms, but very few have been fully developed and adopted for routine, operational processing of global data. For operational data processing, the assumption is made that only a single cloud layer is present in any individual field of view (FOV). Both surface observations and spaceborne lidar or radar measurements indicate that multilayered clouds occur frequently. If the uppermost cloud layer is optically thick, then a passive satellite sensor cannot sense the presence of lower level cloud layers. If, however, the upper cloud layer is optically thin, such as cirrus, then there is some potential for the presence of a lower level cloud layer to modify the radiances observed by the satellite sensor, causing errors in the assessment of the cloud properties for that FOV.

Another assumption generally made when inferring the cloud height is that there is a well-defined cloud-top boundary. For low-level water clouds, such as stratocumulus or cumulus, the cloud-top boundary is well defined. For high-level clouds, such as cirrus, this assumption is more problematic as the cirrus layer can be geometrically thick but with very sparse ice particles throughout the layer, which is another way of saying the cloud is optically thin.

The clouds that require the most attention in operational retrievals are those that reside either near the tropopause (high-level clouds) or near the surface. Some low-level clouds occur in atmospheres with temperature inversions. Proper placement of cloud-top heights requires that there be some knowledge of the atmospheric temperature profile, and numerical models are somewhat deficient on this in many cases. Given the many assumptions that need to be made, e.g., that an FOV contains only a single-layered cloud, is not optically thin at the top of the cloud layer, and that the temperature profile contains no surprises, there are some general approaches to inferring cloud height that are in use.

On many satellite platforms, measurements are obtained at wavelengths located in the 15- μm wavelength region, a region in which atmospheric transmission is dominated by atmospheric CO_2 . As the wavelength increases from 13.3 to 15 μm , the atmosphere becomes more opaque due to CO_2 absorption, thereby causing each channel to be sensitive to a different portion of the atmosphere. This sensitivity is demonstrated in Figure 1, which shows weighting functions at several Moderate Resolution Imaging Spectroradiometer (MODIS) channels located at wavelengths ranging from 12 to 14 μm . Each channel has a peak in its weighting function that occurs at a different pressure level than the other channels. The 12- μm channel is shown for comparison – note that its weighting function peaks at the surface. This is a ‘window’ channel that is insensitive to CO_2 . In the 1970s, Moustafa Chahine, William Smith Sr., and Martin Platt developed a technique known as CO_2 slicing to infer cloud-top pressure from radiances measured at wavelengths between 13.3 and 14.2 μm . In principle, the CO_2 slicing method is based on the

Figure 1 Weighting functions that are derived for MODIS wavelengths ranging from 12 to 14.2 μm . The weighting function is the derivative of the transmittance profile as a function of pressure. The peak in the weighting function provides an indication of what levels in the atmosphere provide most of the upwelling radiance that will be measured by a satellite.

following relation derived from the theory of radiative transfer:

$$\frac{R(v_1) - R_{\text{clear}}(v_1)}{R(v_2) - R_{\text{clear}}(v_2)} = \frac{N'_1 \int_{P_0}^{P_c} \Gamma(P, v_1) \{ \partial B[T(P), v_1] / \partial P \} dP}{N'_2 \int_{P_0}^{P_c} \Gamma(P, v_2) \{ \partial B[T(P), v_2] / \partial P \} dP}, \quad [1]$$

where $R(v_1)$ and $R(v_2)$ are the radiances measured at two channels centered at wave numbers v_1 and v_2 , whereas $R_{\text{clear}}(v_1)$ and $R_{\text{clear}}(v_2)$ are the corresponding clear-sky radiances. The terms Γ , T , and P indicate the transmissivity, temperature, and pressure, respectively. P_0 and P_c indicate the pressure values at the surface and cloud top, respectively. N' denotes the effective cloud amount that is the product of the cloud fraction and the cloud emissivity. If the two channels are selected to be sufficiently close in wave number, the corresponding effective cloud amount values are approximately the same. In this case, it is straightforward to find an appropriate value for the cloud-top pressure P_c by assuring the equality in eqn [1].

The pressure at cloud level is converted to cloud height and cloud temperature through the use of gridded meteorological products that provide temperature profiles at some nominal vertical resolution every 6 h. One benefit to this algorithm is that cloud properties are derived similarly for both daytime and nighttime conditions as the IR method is independent of solar illumination. This approach is very useful for the analysis of midlevel to high-level clouds and even optically thin clouds such as cirrus. The drawback to the use of the 15- μm channel is that the signal-to-noise ratio becomes small for clouds occurring in the lowest 3 km of the atmosphere, making retrievals problematic for low-level clouds. When low clouds are present, the 11- μm channel (also a window channel) is used to infer cloud height.

Cloud Thermodynamic Phase

While the cloud phase is extremely important in radiative transfer simulations of clouds and the retrieval of cloud properties, it is not always straightforward to determine a cloud's phase. If the cloud is located in the upper troposphere where the temperatures are extremely cold, it is assumed to be composed of ice. Conversely, if the cloud is located in the boundary layer over warm surfaces, it is assumed to be water. The difficulty lies in the inference of phase when the cloud-top temperature lies between 233 and 273 K. If the cloud temperature is below 233 K, the homogeneous nucleation temperature, it will be composed of ice. If the cloud temperature is above 273 K, it will be composed of water. If the cloud has a temperature between 233 and 273 K, it could be ice, water, or some mixture of both. In the high-latitude storm tracks in either hemisphere, large-scale stratiform cloud decks tend to form with cloud-top temperatures in the 250–265 K range, and cloud phase is quite difficult to discern.

At temperatures below 273 K, the supersaturation of ice is much higher than the supersaturation with respect to water. If water vapor is present in an atmospheric layer at a temperature in this range, say 260 K, and both water and ice particles are present in this layer, the water vapor will preferentially condense on the ice particles rather than the water particles. As the ice particles become larger, which occur over the course

of seconds to minutes, the growing ice particles will begin to fall through the cloud layer. In this situation, the top of the cloud layer tends to be populated primarily by very small water droplets, while ice particles fall through the cloud base. The cloud layer may contain both ice and water particles, so inference of the cloud phase from satellite data under these conditions is quite challenging.

Two simple approaches are discussed here to infer cloud phase from the radiometric observations made by a passive sensor. One method involves IR radiances measured at 8.5 and 11 μm . The radiances are converted to BTs through the Planck function, and the phase is inferred from the brightness temperature difference (BTD) between the 8.5 and 11 μm BTs (BTD[8.5–11]) as well as the 11 μm BT. Ice clouds exhibit positive BTD[8.5–11] values, whereas water clouds tend to exhibit highly negative values. There are three contributing factors to the behavior of the BTD[8.5–11] for ice and water clouds. First, the imaginary component of the index of refraction (m_i) differs for ice and water at these two wavelengths. Second, while the atmosphere is relatively transparent to gaseous absorption, absorption by water vapor in the atmospheric column above the cloud can still exert a considerable effect on the BTD values. As most of the atmospheric water vapor resides in the lower layers of the atmosphere near the surface, the BTD[8.5–11] values will be most affected in moist atmospheres rather than high-level clouds that reside above most of the water vapor. Third, while a small effect, cloud particles scatter radiation even at the IR wavelengths, and clouds with smaller particles will tend to scatter more radiation than those with larger particles. Multiple-scattering radiative transfer calculations show that for ice clouds, the BTD[8.5–11] values tend to be positive in sign, whereas for low-level water clouds, the BTD[8.5–11] values tend to be very negative (< -2 K).

This simple BTD approach with IR channels can be improved for optically thin ice cloud discrimination by calculating cloud emissivity ratios. In the simplest terms, the cloud emissivity for a channel is based on three numbers: the measured cloud radiance, the black cloud radiance, and the calculated clear-sky radiance. The term 'black' here means that the cloud radiates as a blackbody, which implies that it is opaque at the wavelength of the observation. This is more complicated than a simple BTD approach above because it requires the use of a radiative transfer model (RTM) to provide the clear-sky and black cloud radiances. However, what this approach provides is much more sensitive to optically thin ice clouds. The IR methods are not very useful when supercooled water clouds are present, however, since it is problematic to discriminate between water and ice as discussed previously.

One way to improve the discrimination between water and ice clouds is to analyze reflectances obtained at a VIS wavelength and a shortwave-infrared (SWIR) wavelength (e.g., 0.65 and 1.64 μm , respectively). At wavelengths less than about 0.7 μm , clouds composed of either liquid or ice tend to absorb very little solar radiation. However, at 1.64 μm (and 2.15 μm), the m_i values for both water and ice increase in comparison with those at the VIS wavelength and diverge, with m_i for ice being greater than the value of m_i for water. From this line of reasoning, one might expect that for two different clouds (one ice and one water) of similar particle size and habit (or particle

shape) distributions, the cloud reflectance at $0.65\ \mu\text{m}$ would not depend on thermodynamic phase, whereas the cloud reflectance at $1.64\ \mu\text{m}$ would. In theory and in practice, the $1.64\ \mu\text{m}$ (and $2.15\ \mu\text{m}$) reflectances are much lower for a cloud composed of ice than water particles.

The observations made by an active spaceborne sensor, for example, the Cloud–Aerosol Lidar with Orthogonal Polarization (CALIOP) on the Cloud–Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) platform can be used to effectively determine the cloud thermodynamic phase. The CALIOP 532-nm channel measurements offer polarization capabilities. Two quantities, the layer-integrated backscatter (γ') and the layer-integrated depolarization ratio (δ) can be employed to effectively discriminate cloud thermodynamic phase, which are defined as follows:

$$\gamma' = \int_{\text{cloud top}}^{\text{cloud base}} [\beta'_{\perp}(z) + \beta'_{\parallel}(z)] dz, \quad [2]$$

$$\delta = \frac{\int_{\text{cloud top}}^{\text{cloud base}} \beta'_{\perp}(z) dz}{\int_{\text{cloud top}}^{\text{cloud base}} \beta'_{\parallel}(z) dz}, \quad [3]$$

where $\beta'_{\perp}(z)$ and $\beta'_{\parallel}(z)$ indicate the vertical backscatter profiles associated with the perpendicular and parallel components, respectively. For a given cloudy scene, the γ' – δ relationship can be used to distinguish cloud phase. As illustrated in the right

panel of Figure 2 (the physical concept was originally developed by Yongxiang Hu at NASA Langley Research Center), water cloud pixels correspond to a γ' – δ relationship with a positive slope, whereas a γ' – δ relationship with a negative slope is related to ice cloud pixels. Furthermore, in the case of ice cloud pixels, the upper left branch of the γ' – δ curve corresponds to ice clouds containing horizontally oriented ice crystals, whereas the lower right branch of the γ' – δ curve is related to ice clouds composed of randomly oriented ice particles. The right panel of Figure 2 shows the frequency of occurrence of the γ' – δ relations of ice clouds based on the CALIOP data collected from July through December 2006.

Cloud Optical Thickness and Particle Size

The basic retrieval methodology for inferring the optical thickness and effective particle size is to (1) employ a RTM to develop a lookup table (LUT) for a wide range of assumed cloud properties and viewing geometries and subsequently (2) compare the measured radiances for selected wavelength channels to values in the LUT. The RTM requires a set of single-scattering properties for the cloud layer, which includes the single-scattering albedo, the scattering phase function, the scattering–absorption–extinction efficiencies, and the asymmetry factor. These parameters essentially determine how much incident radiation is reflected or absorbed by the cloud. The single-scattering albedo is defined as the ratio of the portion of energy scattered by a particle to the total extinction

Figure 2 Left panel: schematic diagram showing the γ' – δ relationships for water and ice cloud pixels. Right panel: γ' – δ relationships based on the CALIOP measurements in the case when the lidar beam was pointed within 0.3° from the nadir.

(scattering + absorption) of energy by the particle. The phase function specifies the percentage of radiative energy that is not absorbed but is instead redistributed by the action of scattering by cloud particles when radiation impinges on clouds. The asymmetry factor describes the ratio of forward scattered to backscattered energy and is a quantity often used in radiative flux calculations. In practice, the single-scattering albedo and the asymmetry factor are parameterized in terms of analytical functions (normally polynomials) that depend on particle effective size for both water and ice clouds. In many RTMs, the radiative properties of clouds are described in terms of particle effective size and either liquid or ice water content (LWC or IWC), depending on the cloud phase. Cloud optical thickness and particle effective size are critically dependent on the accurate determination of the cloud bulk radiative properties, and a focus of recent research has been to improve the description of ice clouds in RTMs.

Various methods have been suggested to derive the optical thickness and effective particle size based on narrowband radiometer measurements by airborne- or satellite-based imagers. Operational methods tend to rely on IR bands or a combination of VIS and SWIR bands. The IR approach depends on the spectral information from thermal emission of clouds, whereas the VIS–SWIR approach is based on the reflection of solar radiation. Teruyuki Nakajima and Michael King were among the first to use reflected solar radiation to simultaneously retrieve cloud optical thickness and effective particle size for water clouds. The typical IR technique employs the BT or BTD values based on window channels at 8.5, 11, and 12 μm . Regardless of the detailed spectral information involved in these two methods, they are similar in that both depend on comparison of measured radiance data with simulated radiances derived for similar viewing and atmospheric conditions.

The first step in this process is to discuss the generation of reliable libraries of simulated cloud and clear-sky radiances. Single-scattering calculations must be carried out regarding how individual cloud particles interact with incident radiation. For water clouds, the liquid droplets can be well approximated as spheres for light scattering. The scattering properties of an individual liquid sphere can be calculated by using the well-known Lorenz-Mie theory that has been documented in many texts. James Hansen and Larry Travis have extensively discussed the effect of size distribution on single-scattering properties of spheres. Their work provides a theoretical framework for using and applying the bulk radiative properties of liquid droplet distributions which is briefly recaptured here.

Within a given water cloud, liquid water droplets span a range of sizes that may be represented mathematically in terms of the Gamma distribution, given by

$$n(r) = \frac{N_0 (r_{\text{eff}} V_{\text{eff}})^{(V_{\text{eff}}-1)/V_{\text{eff}}}}{\Gamma[(1-2V_{\text{eff}})/V_{\text{eff}}]} r^{(1-3V_{\text{eff}})/V_{\text{eff}}} \exp(-r/r_{\text{eff}} V_{\text{eff}}), \quad [4]$$

where N_0 is the total number of the droplets in a unit volume; r_{eff} and V_{eff} are the effective radius and effective variance that are defined, respectively, as follows:

$$r_{\text{eff}} = \frac{\int_{r_1}^{r_2} r^3 n(r) dr}{\int_{r_1}^{r_2} r^2 n(r) dr}, \quad [5]$$

$$V_{\text{eff}} = \frac{\int_{r_1}^{r_2} (r - r_{\text{eff}})^2 r^2 n(r) dr}{r_{\text{eff}}^2 \int_{r_1}^{r_2} r^2 n(r) dr}. \quad [6]$$

In a plot of the Gamma distribution, the peak of the distribution defines the r_{eff} , while V_{eff} affects the width of the distribution. Typical values of the effective variance for water clouds range from 0.05 to 0.1. For a given size distribution, the bulk-scattering properties of cloud droplets may be calculated. For example, the phase function averaged over a size distribution is given by

$$\langle P(\theta) \rangle = \frac{\int_{r_1}^{r_2} \sigma_s(r) P(\theta, r) n(r) dr}{\int_{r_1}^{r_2} \sigma_s(r) n(r) dr}, \quad [7]$$

where σ_s is scattering cross section of droplets and $P(\theta, r)$ is the phase function for droplets with radii of r , which describes the angular distribution of scattered radiation versus scattering angle θ .

Figure 3 shows the phase functions averaged for size distributions for water clouds at wavelengths 0.65, 1.63, and 11 μm . For the 0.65- μm wavelength, the phase function displays scattering maxima at 140 and 180°. Physically, the two maxima are due to mechanisms associated with the rainbow and glory, both characteristic features of Mie scattering. The phase functions at the SWIR wavelength (1.63 μm) are similar to those at 0.65 μm , but the rainbow and glory maxima are somewhat reduced by absorption within the particle. At the IR wavelength of 11 μm , the scattering maxima of the phase function are largely smoothed out due to absorption within the water droplets.

Another measure of the relative amounts of scattering versus absorption is provided by the single-scattering albedo. At 0.65 μm , the scattering of incident radiation by cloud droplets is conservative, meaning that energy may be scattered, but not absorbed, by the particles. Thus, the single-scattering albedo is unity at 0.65 μm but less than unity at 1.63 μm . The particle size also affects the single-scattering albedo at 1.63 μm . For example, for effective sizes 4 and 32 μm , the particle single-scattering albedo is unity at 0.65 μm , whereas the corresponding values at 1.63 μm are 0.9976 and 0.9824, respectively. Because of the difference in single-scattering albedo at the two wavelengths, reflection by an optically thick cloud at 0.65 μm is essentially a function of optical thickness. At 1.63 μm , however, cloud reflectance is sensitive to droplet effective size. This feature of cloud reflectance provides a mechanism to retrieve cloud optical thickness and particle sizes using two channels at VIS and SWIR wavelengths, as will be further explained later in this section.

Ice clouds are almost exclusively composed of nonspherical ice particles with various sizes and habits (i.e., shapes). Ice particles can consist of relatively simple shapes such as bullet rosettes, columns, and plates or more complex shapes such as aggregates of columns or plates. Most of the columnar particles can have hollow intrusions at the ends, which is caused by preferential molecular deposition onto a growing particle. In an environment where supercooled water droplets are present, the ice particles can also become rimed, which increases an individual particle's surface roughness. An increasing amount of research is showing that the consistency of inferred ice cloud properties improves between algorithms using solar, IR, or

Figure 3 Scattering phase function of water droplets calculated at three wavelengths at 0.65, 1.63, and 11 μm for effective radii of 4, 8, and 16 μm .

polarized measurements if an assumption of ice particle severe surface roughening is adopted.

Research is underway to determine how to accurately calculate the single-scattering properties of a limited set of idealized ice habits. In practice, methods such as the discrete dipole approximation, finite-difference time domain technique, or the T-matrix method are used to calculate the scattering properties of a given habit for which the ratio of the particle circumference to the wavelength (also known as the size parameter) is small, i.e., less than 30. For ice particles

with larger size parameters, scattering calculations are performed using a ray-tracing technique based on the principles of geometric optics.

Figure 4 shows the phase matrices at 0.65- μm wavelength for two types of ice crystals: a solid column with smooth surfaces and aggregates of plates with rough surface. The phase function of smooth hexagonal columns displays a strong scattering peak at 22° and is produced by the hexagonal structure typical of ice crystals. In addition to the peak at 22° , the phase function of solid columns also displays a small peak

Figure 4 The scattering phase matrices of hexagonal ice crystals with smooth surface and aggregates of plates with rough surfaces.

corresponding to a 46° halo. Compared to the phase function for pristine crystal habits, the phase function for aggregates of plates is essentially featureless due to the severely roughened surface texture. The rougher the particle, the more featureless is the phase function. The other nonzero elements of the phase matrix are related to the polarization state of the scattered light. The impact of surface roughness on the polarization state is significant. Some recent studies have demonstrated that polarization measurements, for example, by the Polarization and Anisotropy of Reflectances for Atmospheric Sciences coupled with Observations from a Lidar (PARASOL) offer unprecedented capabilities to infer ice crystal habit and associated particle roughness. In particular, the comparison between the polarized reflectance observed by PARASOL and the relevant theoretical simulations illustrates that the closest match occurs when assuming the presence of ice crystals with severely roughened surfaces.

In reality, ice clouds are composed of many different crystal habits. To derive the bulk radiative properties of cirrus clouds, we need to consider not only a particle size distribution but also the percentages of the various particle habits that comprise the cloud. For this reason, the derivation of accurate radiative transfer simulations of ice clouds is considered more difficult than for water clouds. For a given size distribution, a number of definitions have been suggested for the effective size. If the effective size is defined as the ratio of total volume to total projected area, however, the bulk optical properties are insensitive to the detailed structure of the size distribution. The effective radius is then

$$r_{\text{eff}} = \frac{3 \int \sum_i f_i V_i(D) n(D) dD}{4 \int \sum_i f_i A_i(D) n(D) dD}, \quad [8]$$

where D is the maximum dimension of an ice particle, f_i is the habit fraction, V and A are the volume and projected area for

individual particle, and n is the particle number concentration. Based on *in situ* measurements within ice clouds, a modified gamma distribution is used most often to describe the particle size distribution.

In situ ice cloud measurements are now available from numerous field campaigns based at locations around the world. For example, Table 1 (data courtesy of Andrew Heymsfield, National Center for Atmospheric Research) lists a number of the particle size distributions obtained at various field campaigns and the instruments used for the microphysical measurements. This is by no means a complete list. A new generation of sensors is beginning to provide measurements of the smallest particles in a given particle population and even a sense of the particle roughening. *In situ* measurements indicate that the effective radius of ice crystals in cirrus clouds may range from about $5 \mu\text{m}$ (small ice particles near the tropopause) to more than $100 \mu\text{m}$ (deep convection). Larger particle radii might be expected for ice clouds formed in convective situations where the updraft velocity is much higher (m s^{-1}) than that found under conditions where optically thin cirrus tend to form (cm s^{-1}). The *in situ* measurements provide insight for the development of an appropriate ice cloud model in terms of the ice crystal habit and size distributions. As an example, the upper left panel of Figure 5 illustrates an ice model based on two habits (hexagonal columns and aggregates of plates) with surface roughness. The lower left panel of Figure 5 shows the comparisons of the computed medium mass diameter (where half the mass is in smaller particles and half in larger particles) versus *in situ* measurements, whereas the lower right panel shows the corresponding comparison for IWC. Apparently, the two-habit model can reasonably represent *in situ* microphysical measurements. The upper right panel of Figure 5 shows the phase function based on the two-habit model in comparison with the MODIS Collection 5 counterpart. Note that the asymmetry factors associated with the two

phase functions are quite different; particularly, the asymmetry factor for the two-habit model is approximately 0.76, whereas the MODIS Collection 5 counterpart is 0.82.

Given the single-scattering properties, radiative transfer computations can be carried out for various cloud optical

thickness and effective particle sizes for a number of solar and viewing geometry configurations. To calculate the bidirectional radiance of clouds, one can use well-established discrete ordinate or adding-doubling methods. Figure 6 shows the correlation of 2.13- μm reflectance and 0.86- μm reflectance of cirrus

Figure 6 The theoretical relationship between the reflection function at 0.86 and 2.13 μm for various values of cloud optical thickness and effective particle size.

clouds for a number of optical thickness and effective sizes for a given incident-view geometry. At higher optical thicknesses (meaning the cloud is more opaque), there is a 'quasi-orthogonality' between the optical thickness and particle size curves. As we have mentioned previously, the cloud reflectance at 0.86 μm is primarily sensitive to cloud optical thickness, whereas the reflectance at 2.13 μm is sensitive to both the particle size and cloud optical thickness. This orthogonality forms the underlying principle for application of the two-channel correlation technique for retrieving cloud optical thickness and effective size. For example, assume the symbol 'X' in Figure 6 to represent the (0.86 and 2.13 μm) reflectivity pair. One may infer that the corresponding optical thickness is approximately 14, whereas the effective particle size is 25 μm . It should be pointed out that, in practice, the (0.86 and 2.13 μm) reflectivity combination is usually used for retrieval over ocean, the (0.64 and 2.13 μm) reflectivity combination is used for over land, and the (1.24 and 2.13 μm) reflectivity combination is used over snow or ice. In addition to the 2.13- μm channel, a channel located at 1.64 or 3.7 μm can be used as the SWIR or MWIR channel involved in the aforementioned bispectral method.

As an alternative or as a complement to the VIS-SWIR bispectral retrieval algorithm, IR channels in the window region (8–12 μm) may be used for retrieving cloud properties. The window region is an important part of the IR spectrum because terrestrial thermal emission peaks within this spectral region. IR-based methods are useful because a single approach may be used for both daytime and nighttime conditions, thereby simplifying the data reduction effort and also the comparison between daytime and nighttime cloud properties. IR methods are insensitive to sun glint over water that is often present in operational data. Interpretation of data over reflective surfaces is often performed more readily using IR methods rather than

those that involve VIS-SWIR wavelengths. The underlying principle for IR retrievals is based on the sensitivity of the BT or the cloud emissivity (related to blackbody or graybody emission) to cloud optical thickness and particle size. The BT is the temperature that, when applied to the calculation of Planck function for blackbody radiation, gives the same value as the satellite measured IR radiance. Figure 7 illustrates the sensitivity of the BT between the 11- and 12- μm channels as a function of the BT at the 11- μm channel for various cloud optical thickness and the effective particle size. Evidently, comparing the measurements of the BTD-BT relation with the theoretical computations permit simultaneous retrieval of cloud optical thickness and the effective particle size. However, the IR technique is more sensitive to the atmospheric profile (particularly, the temperature profile) and the surface emissivity than the VIS-SWIR technique.

In addition to the use of BDT and BT, a quantity known as the cloud emissivity has been widely used to infer cloud properties. In practice, the cloud emissivity can be calculated as follows:

$$\varepsilon(\lambda) = \frac{R(B) - R}{R(B) - R(C)}, \quad [9]$$

where R is the upwelling radiance at the cloud top, $R(B)$ is the upwelling radiance at the cloud bottom, and $R(C)$ is the upwelling blackbody radiance corresponding to the cloud temperature. In practice, for a given scene, the radiance at cloud base can be obtained by the noncloudy (i.e., clear sky) pixels.

Furthermore, the IR techniques for retrieving ice cloud properties are less sensitive than their VIS-SWIR counterparts to ice crystal habits assumed in the forward light-scattering and radiative transfer simulations. To illustrate this point, panels (a) and (b) of Figure 8 show the phase functions of two ice crystal habits (hexagonal columns and hollow bullet rosettes)

Figure 7 The variation of the BT between the 8.5- and 12- μm channels as a function of the BT at the 11- μm channel.

Figure 8 Panel (a): bulk phase functions of solid columns and hollow bullet rosette with an effective particle size of 50 μm at 0.86 μm . The gamma distribution is used to simulate the size distribution. Panel (b): similar to panel (a) except for a wavelength of 11 μm . Panel (c): comparison of cloud optical thickness retrievals based on the VIS-SWIR retrieval on the basis of a solid column habit model and a hollow bullet rosette habit model. Panel (d): similar to panel (c) except that an IR technique is used.

at wavelengths of 0.86 and 11 μm , respectively. Substantial differences are noticeable at the 0.86- μm near IR wavelength, whereas the two phase functions are quite similar at the 11- μm wavelength. Panel (c) of [Figure 8](#) compares the optical thickness values retrieved with the VIS–SWIR bispectral method based on MODIS Band 2 (0.86 μm) and Band 7 (2.13 μm) measurements. The impact of the assumed ice crystal habit on the retrieval is obvious from panel (c). The optical thickness values retrieved from the IR technique are shown in panel (d) based on the MODIS Band 29 (8.5 μm), Band 31 (11 μm), and Band 32 (12 μm) observations. The effect of ice crystal habit on the IR-based technique is negligible.

Cloud radiative and microphysical properties are cloud inherent properties that should be independent of a specific retrieval algorithm employed to infer the cloud properties. In this sense, the VIS–SWIR and IR retrievals should be consistent. The spectral consistency of cloud property retrievals is critical to some analyses, particularly, the study of the diurnal variations of cloud properties based on a VIS–SWIR algorithm for daytime and an IR algorithm for nighttime. In the case of ice cloud, recent studies have demonstrated that the ice cloud optical model involved in the forward radiative transfer simulation is essential for achieving spectral consistency.

Future Challenges in Cloud Property Retrieval

Current efforts to derive a global cloud climatology from satellite data generally do not account properly for multiple cloud layers in pixel-level imager data. To date, operational algorithms are designed to infer cloud properties for each imager pixel under the assumption that only one cloud layer is present. Climatologies of retrieved cloud properties do not address the effect of an optically thin upper cloud layer, such as cirrus, that may overlay a lower cloud layer such as a cumuli-form cloud deck. Surface observations show that clouds often occur in multiple layers simultaneously in a vertical column, i.e., cloud layers often overlap. Multiple cloud layers occur in about half of all cloud observations and are generally present in the vicinity of midlatitude fronts and in the tropics where cirrus anvils may spread hundreds of kilometers from the center of convective activity. When multilayered clouds are present, the retrieval algorithms will generally place the cloud layer at a height between the two (or more) actual layers present in the FOV. Currently, available satellite cloud climatologies provide a horizontal distribution of clouds but need improvement in the description of vertical distribution of clouds. At this point, a reliable method has not been developed for the retrieval of cloud properties (optical thickness, cloud thermodynamic phase, and effective particle size) when multilayered, overlapping clouds are present.

Even for a single-layered cloud, satellite retrieval algorithms do not account for the effect of a likely vertical variation of cloud microphysical properties, which in turn will decrease the ability of radiative transfer calculations to accurately simulate the cloud. It is unlikely that cloud particles are homogeneously distributed throughout any given cloud. For example, ice crystal size and habit are typically quite different for midlatitude cirrus at cloud top from at cloud base. A common assumption in satellite imager-based cirrus retrieval algorithms is that the radiative properties of a cirrus cloud may be

represented by those associated with a specific ice crystal shape (or habit) and a single particle size distribution. However, observations of synoptic cirrus clouds with low updraft velocities have shown that pristine small ice crystals with hexagonal shapes having an aspect ratio close to unity (length and width are approximately equal) are predominant in top layers. The middle layers of cirrus are often composed of well-defined columns and plates, while irregular polycrystals or aggregates are dominant near cloud base. This picture is quite different from ice particles that form in deep convection; in this case, the population of ice particles may be dominated by complex aggregates.

Another interesting area of complexity in satellite remote sensing is caused by mixed-phase clouds. Single-layered clouds composed of mixtures of supercooled water droplets and ice particles have been observed frequently during various field campaigns. Recent analyses of these data and MODIS satellite cloud property retrievals highlight the difficulty of ascertaining phase. If mixed-phase clouds are present in the data, one might expect larger errors in retrieved properties such as optical thickness and particle size than clouds that are primarily of a single phase. From the perspective of satellite remote sensing, the working assumption is that any imager pixel contains either ice or water but not a mixture. There is no rigorous method available for determining the single-scattering properties of mixed-phase clouds. From the microphysical cloud process perspective that is important for developing cloud model parameterizations, the presence of both ice particles and supercooled water droplets will affect cloud lifetime. Why? It is likely that the ice particles will grow much more quickly from vapor deposition than the water droplets as the environment may be supersaturated with respect to ice. The result of this process is that the ice particles will rime, grow quickly in size, and fall through the cloud, and the available water will be depleted quickly. The process of glaciation is very important for modelers because the water–ice conversion rates affect cloud lifetime. Details of cloud microphysics, such as cloud water amount, cloud ice amount, snow, graupel, and hail, are important for improving cloud retrieval.

While approaches exist to retrieve a variety of cloud properties from satellite imager data, it is not an easy problem to compare the satellite retrievals with ground-based measurements of the same cloud. Comparisons are often attempted between a surface-based measurement at a fixed location over a long temporal period and satellite measurements that provide an instantaneous measurement over a wide area. While difficult and often creative, confidence in retrievals is often gained through painstaking comparison between the two. For some cloud properties, it may be possible to compare properties derived from two or more different satellite instruments. This will be one of the more active areas in future research.

Synopsis

Research satellites have been developed for measuring the properties of the Earth's atmosphere since 1960, with increasingly sophisticated instrumentation and attention to calibration and radiometric accuracy. Among the properties of the Earth's atmosphere that are routinely observed from space are (1) the Earth's radiant energy budget (the balance between the shortwave energy entering the Earth and the outgoing radiation leaving the Earth), (2) aerosol particles (dust, pollution, smoke), (3) cloud properties (frequency of occurrence, height, size of cloud particles), (4) chemical constituents (ozone, nitrogen dioxide, sulfur dioxide), (5) atmospheric temperature and water vapor, and (6) precipitation.

Introduction

The atmosphere changes chemically and physically on widely varying timescales – ranging from minutes to decades – and is therefore a challenge to measure precisely over the entire globe. But with the National Aeronautics and Space Administration's (NASA) 1960 launch of the Television Infrared Observation Satellite, Earth scientists began a new mission to observe large-scale weather patterns from space. In the late 1970s, their mission expanded to include global-scale measurements that would help them understand the causes and effects of longer term climate change. NASA and its affiliated agencies and research institutions collaborated to develop a series of research satellites that have enabled scientists to test new remote-sensing technologies that have advanced scientific understanding of both chemical and physical changes in the atmosphere. ('Remote sensing' involves the use of devices other than our eyes to observe or measure things from a distance without disturbing the intervening medium.) The goal is to examine our world comprehensively to determine what dynamics drive our planet's climate system and how climate change affects, and is affected by, our environment.

Depending on their measurement objectives, research satellites primarily fly in one of two orbits: (1) a near-polar, sun-synchronous orbit to allow their sensors to observe the entire globe at the same solar time each day, or (2) a mid-inclination, precessing orbit to focus their sensors on the equator and lower latitudes where the observations are made at different times of day to better sample time-varying phenomena such as clouds. Some polar-orbiting satellite sensors can observe any given place on the globe as often as every day, thus collecting data with high temporal (time) resolution. Other satellite sensors view any given place as infrequently as once every 16 days, thus having relatively low temporal resolution for a satellite sensor, but still far surpassing our ability to make these same measurements with surface-based or aircraft sensors. Satellite sensors with high spatial resolution (15 m per pixel) can discern objects in the atmosphere or on the surface as small as say a football field or farmland, thus providing high spatial resolution. Other satellite sensors that are designed to measure continental and global-scale dynamics typically have only moderate (500 m per pixel) to low (20 km per pixel) spatial resolution. Satellite sensors carry specially designed detectors that are particularly sensitive to certain wavelengths of the electromagnetic

spectrum, called spectral bands. The more precisely a remote sensor can measure narrow bands of radiant energy, and the greater the number of these discrete bands it can measure, the higher is its spectral resolution. The atmosphere interacts with solar radiation much like a venetian blind – selectively absorbing and reflecting certain wavelengths of solar energy while allowing others to pass through. Engineers design satellite remote sensors to be particularly sensitive to those wavelengths that can be reflected or emitted back up through the atmosphere to space, thus enabling them to make their measurements.

Earth-orbiting remote sensors provide the best means of collecting the data scientists need because they can measure things on scales of time and space that otherwise would not be possible. Moreover, satellite sensors not only observe wavelengths of visible light but also precisely measure wavelengths of radiant energy that our eyes cannot see, such as microwaves, ultraviolet rays, or infrared light. If scientists know how certain objects (like cirrus clouds or windblown dust) typically absorb, reflect, and emit particular wavelengths of radiant energy, then by using satellite sensors to precisely measure those specific bands of the electromagnetic spectrum, scientists can learn a lot about the Earth's atmosphere and surface. Remote sensors allow us to observe and quantify key climate and environmental vital signs such as temperature, ozone concentrations, carbon monoxide (CO) and other pollutants, water vapor and other greenhouse gases, cloud cover and their properties (height, optical thickness, phase, cloud particle size), aerosol concentrations, radiant energy fluxes, and many more.

Balancing Earth's Radiant Energy Budget

Climate is defined as the average state of the atmosphere, hydrosphere, and land over a given time period. Thus, measurements of radiant energy within the Earth's atmosphere are at the heart of the climate change discussion. How the climate changes is directly related to how our planet balances the amount of incoming sunlight with outgoing radiant energy. For scientists, to measure all incoming and outgoing energy is to have a bottom line ledger sheet on the sum total of all the physical motions and interactions of our world's climate system. Over the course of a year and over the entire globe, is the Earth's total energy budget in balance? If not, the Earth is either heating up or cooling down. So if scientists are to

Figure 1 Global net radiation at the top of the Earth's atmosphere measured by CERES on Terra and Aqua on January 2010 (top) and July 2010 (bottom).

understand climate and accurately predict future climate change, then they must determine what drives the changes within the Earth's radiation balance.

In 1978, NASA launched its Nimbus-7 satellite carrying a new sensor, called the Earth Radiation Budget (ERB) experiment, designed to measure direct solar irradiance, reflected shortwave radiation (visible light), and emitted longwave radiation (heat) every day over the entire Earth. This was the first space-based sensor capable of self-calibrating so that its total solar irradiance measurements were accurate to within $\pm 0.5\%$. The Nimbus-7 ERB collected 9 years of global-scale data on which scientists began long-term climate studies. In the interest of extending the ERB data set and improving its measurement capabilities, NASA launched three more Earth Radiation Budget Experiments (renamed ERBE) in the 1980s.

In addition to total solar irradiance, ERBE measured the reflected solar and emitted thermal radiation from the Earth-atmosphere-ocean system. These observations revealed that over the course of a year, the global radiation budget is in balance – the Earth reflects and emits roughly the same amount of energy back into space that it receives from the sun. The data also showed that the average annual, global contribution by clouds is that they reflect 17 W m^{-2} more shortwave energy (visible light) than they trap as longwave energy (heat). Yet, due to calibration uncertainties, deficiencies in ERBE's sampling method, and the

limitations of existing angular dependence models, there still exists a significant uncertainty (about $\pm 5 \text{ W m}^{-2}$) regarding our understanding of Earth's radiation budget. Part of this uncertainty lies in our limited knowledge of the spatial distribution of clouds as well as the optical properties of these clouds over time. Moreover, we cannot be sure how the distribution and optical properties of clouds will change over time. The endeavor to address these issues began with the 1997 launch of the Clouds and the Earth's Radiant Energy System (CERES) sensor aboard the joint NASA/NASDA (National Association of State Departments of Agriculture) Tropical Rainfall Measuring Mission (TRMM) satellite. Twin CERES instruments were also launched aboard NASA's Terra satellite in December 1999 and NASA's Aqua satellite launched in May 2002. Many of the sampling and accuracy limitations on ERBE were addressed in the design of CERES so that it allows scientists to meet ERBE's same measurement objectives with better than twice the former sensor's accuracy.

CERES data permit the determination of net radiation (the balance between incoming and outgoing energy at the top of the atmosphere), which is the total energy available to influence the planet. Due to the seasonal shift of the sun, the excess energy into the system moves with the seasons (Figure 1), with excess energy into the Earth-atmosphere system in the Southern Hemisphere in January (Austral summer) and the Northern Hemisphere in July (Boreal summer). Places where

more energy was coming into the system than going out (positive net radiation) are shown in red-orange, whereas places where more energy was going out than coming in (negative net radiation) are shown in blue-green.

Dust in the Wind

Aerosols are tiny particles suspended in the air (mostly in the troposphere). Some aerosols come from natural sources, such as volcanic eruptions, dust storms, forest and grassland fires, living vegetation, and sea spray. About 10% of the total emitted aerosols in our atmosphere come from human activities, such as the burning of vegetation and fossil fuels and changing the natural land surface cover, which again leads to windblown dust. Most of that 10% is concentrated in the Northern Hemisphere, especially downwind of industrial sites. Yet human-produced aerosols account for about half of the total effect of all aerosols on incoming sunlight. From a satellite's perspective, aerosols raise the Earth's albedo, or make it appear brighter by scattering and reflecting sunlight back to space. The overall effect of these tiny particles is to cool the surface by absorbing and reflecting incoming solar radiation. They also serve as cloud condensation nuclei, or 'seeds' for cloud formation, which again helps to cool the surface. In terms of their net influence on global climate, aerosols represent scientists' greatest subject of uncertainty. Yet computer climate models estimate that over the last century, human-produced aerosols have offset some of the global warming due to greenhouse gases from what otherwise would have taken place.

Through the 1980s and most of the 1990s, the NOAA Advanced Very High-Resolution Radiometer (AVHRR) was the most frequently used satellite sensor for measuring aerosol optical thickness. (Aerosol optical thickness is a measure of how much sunlight airborne particles prevent from traveling through a column of atmosphere.) However, AVHRR can only make such measurements over the ocean, as the sensor requires a relatively uniform and dark-colored background. In April 1991, the European Space Agency (ESA) launched a new type of multiangle sensor, called the Along Track Scanning Radiometer (ATSR), aboard their first European Remote-Sensing Satellite (ERS-1). The ATSR makes aerosol optical thickness measurements by remotely sensing visible and near-infrared wavelengths at nadir and oblique forward scan angles (both within a 2-min interval). A modified version of the sensor, called the Advanced Along Track Scanning Radiometer, was launched in 1995 aboard ERS-2 and 2002 aboard Envisat.

In 1996, Japan launched the first in their series of Advanced Earth Observation Satellites (ADEOS) satellites, which carried a payload of two sensors—the Polarization and Directionality of the Earth's Reflectances (POLDER) sensor, contributed by the French Space Agency, and the Ocean Color and Temperature Scanner, provided by NASDA. Both sensors can retrieve aerosol measurements, but POLDER was the first satellite sensor specifically designed to measure aerosols and it can make its measurements over both land and ocean. The sensor observes Earth targets from 12 directions that enable measurements of the bidirectionality and polarization of solar radiation reflected from within the atmosphere. Unfortunately, due to its solar panel failing, the ADEOS mission ended

prematurely after only 8 months in orbit. A POLDER instrument on the French PARASOL (Polarization and Anisotropy of Reflectances for Atmospheric Sciences coupled with Observations from a Lidar) mission was launched in 2004 and is producing aerosol optical thickness retrievals over both land and ocean.

Three sensors aboard NASA's Terra satellite are particularly well-suited for studying the effects of aerosols on climate: CERES, Multiangle Imaging Spectroradiometer (MISR), and Moderate-Resolution Imaging Spectroradiometer (MODIS). Both the MODIS and the MISR have the capacity to measure both aerosol optical thickness and the sizes of aerosol particles over both ocean and land. Particle size is an indicator of the source of the aerosol particles and helps scientists distinguish aerosols of natural origin from those that are man-made. Moreover, with its nine different look angles, MISR is ideally designed to quantify the reflective properties. Again, CERES complements MODIS and MISR by providing measurements of the shortwave radiation that aerosols reflect back into space. Together, these sensors are providing new insights into the roles of aerosols in the Earth's total energy budget (Figure 2).

Abstract Art or Arbiters of Energy?

More than just the idle stuff of daydreams, clouds help control the flow of radiant energy around our world. Clouds are plentiful and widespread throughout Earth's atmosphere – covering between 66 and 69% of our planet at any given time – so they play a dominant role in determining how much sunlight reaches the surface, how much sunlight is reflected back into space, how and where warmth is spread around the globe, and how much heat escapes from the surface and atmosphere back into space. Clouds are also highly variable. Clouds' myriad variations through time and space make them one of the greatest areas of uncertainty in scientists' understanding and predictions of climate change. In short, they play a central role in our world's climate system. Whereas thick, low-level stratocumulus clouds cool the Earth's surface by reflecting incoming solar radiation, thin high-level cirrus clouds exert a warming influence by allowing sunlight to pass through but then trapping the heat emitted by the surface. Which of clouds' effects is greater over time, warming or cooling? Scientists did not know the answer to that question until relatively recently. Based on ERBE satellite data collected in mid to late 1980s, coupled with aircraft and surface-based measurements, scientists demonstrated that, globally, clouds' cooling effect on the surface is greater than their warming effect. So great is this cooling effect, it is as if clouds remove the heat of a 60-W light bulb from every $2 \times 2 \text{ m}^2$ of the Earth's surface. But will they continue to cool our planet over the next century if a greenhouse gas-driven global warming scenario comes to pass? Or even, could the type and distribution of clouds change so that they primarily exert a warming influence? (Figure 3).

Two sensors flying aboard NASA's Terra satellite, launched in December 1999, are designed to help scientists answer these questions. Both MODIS and MISR give scientists new capabilities for measuring the structure and composition of clouds. MODIS observes the entire Earth almost every day in

Figure 2 Global aerosol optical thickness measured by MODIS on Terra on January 2010 (top) and July 2010 (bottom).

36 spectral bands ranging from visible to thermal infrared wavelengths. With spectral and spatial resolutions superior to that of AVHRR (its heritage sensor), MODIS can measure a wide suite of clouds' physical and radiative properties. Specifically, MODIS can determine whether a cloud is composed of ice or liquid water particles (or some combination of the two), it can measure the effective radius of the particles within a cloud, it can observe how much (or little) sunlight passes through a cloud, and it can measure the temperature and altitude of cloud tops.

Complementing MODIS, the MISR instrument 'sees' the Earth simultaneously in red, green, blue, and near-infrared wavelengths at nine different angles – at four progressively more oblique angles ahead of Terra, four angles aft of the satellite, and one at nadir. Because it measures any given scene from multiple angles, MISR is ideally designed to help scientists better understand how clouds interact with radiant energy as both a function of their structure and type. CERES complements MODIS and MISR by providing measurements of the shortwave and longwave radiant energy that clouds reflect and emit back into space.

Starting in 2006, NASA launched two satellites carrying active sensors to monitor the vertical distribution of clouds and aerosols, and to monitor the water content within those clouds. CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder

Satellite Observations) carried the CALIOP (Cloud-Aerosol Lidar with Orthogonal Polarization) instrument, which is a dual frequency monostatic lidar that sends its own laser pulse down to the Earth and measures the time delay from the return signal scattering by clouds, aerosols, and the Earth's surface, from which it determines the height and often thickness of clouds. This payload was complimentary to the CloudSat satellite that carried its Cloud Profiling Radar. These two nadir-viewing sensors are in the same orbit and only 60 s behind Aqua, which carries the wide-swath MODIS imager. These powerful active sensors are improving our assessment of cloud properties over complicated multilayered clouds and in Polar Regions where it is much more difficult to distinguish clouds from the bright snow-covered surfaces using passive remote-sensing techniques alone.

Serendipity and Stratospheric Ozone

In the early 1970s, as Earth scientists intensified their studies into the possible causes and effects of global warming, a suite of man-made gases in particular elicited the attention of scientists – chlorofluorocarbons (CFCs). Increasingly, CFCs were being used by industrial nations in the production of a variety of commercial products (e.g., refrigerants, aerosol

Figure 3 Global cloud fraction measured by MODIS on Terra on January 2010 (top) and July 2010 (bottom).

sprays). The concern is twofold: CFCs are up to 200 times more efficient than carbon dioxide at trapping heat in the Earth's atmosphere and the gas tends to remain in the atmosphere up to 120 years once released. Then, in 1974, two scientists wrote of a new concern that CFCs could potentially reduce levels of ozone in the stratosphere, the layer of atmosphere from 10 to 50 km in altitude. In 1975, the US Congress asked NASA to develop a 'comprehensive program of research, technology, and monitoring of phenomena of the upper atmosphere. 'In particular, Congress' intent was to ascertain the 'health' of the ozone layer (Figure 4).

So, in addition to ERB, in 1978 Nimbus-7 carried two other new NASA sensors designed to measure the total amount of ozone in a given column of atmosphere over the entire globe – called the Solar Backscatter Ultraviolet instrument and the Total Ozone Mapping Spectrometer (TOMS). Sensitive to radiant energy in the ultraviolet region of the spectrum, these sensors took advantage of the fact that molecules and aerosol particles reflect certain wavelengths of ultraviolet rays while ozone absorbs others at different levels in the atmosphere. By analyzing the amount of ultraviolet energy reflected back up to the spacecraft, researchers could produce profiles of how thick or thin the ozone was at different altitudes and locations. Ironically, it was not until October 1985 that a British team of scientists found a significant reduction in ozone over Halley Bay, Antarctica. Using a ground-based Dobson ozone

spectrophotometer, the team found that the amount of stratospheric ozone over Halley Bay was about 40% less than it had been the previous year. Their finding stunned the science community because they were expecting anthropogenic ozone depletion to occur first at upper levels in the stratosphere (30–50 km) and so they anticipated that the initial signal of depletion in a total column of ozone would be weak. NASA researchers hastily reviewed their TOMS data and found that it too had detected a dramatic loss of ozone over all of Antarctica. Why had not they discovered the phenomenon earlier? Unfortunately, the TOMS data analysis software had been programmed to flag and set aside data points that deviated greatly from expected measurements and so the initial measurements that should have set off alarms were simply overlooked. In short, the TOMS team failed to detect the ozone depletion years earlier because it was much more severe than scientists expected.

In the years following the discovery of the ozone hole, NASA and ESA satellites recorded ozone levels over Antarctica growing worse with each passing year. In response, in 1987, 43 nations signed the 'Montreal Protocol' in which they agreed to reduce the use of CFCs by 50% by the year 2000. This protocol was amended in 1990, 1992, and 1999 to eliminate all CFC emissions by 2000.

ESA's second European Remote-Sensing Satellite (ERS-2) carries a sensor called the Global Ozone Monitoring

Figure 4 The minimum total ozone content of the Southern Hemisphere for selected years between 1979 and 2010, based on data from the TOMS on the Nimbus-7, Meteor 3, and Earth Probe satellites (1979–2003), and the OMI on the EOS Aura satellite (2004 to present). Dobson unit = 2.69×10^{16} molecules cm^{-2} .

Experiment (GOME). GOME is a nadir-looking sensor with four bands ranging from 240 to 790 nm for measuring backscattered visible and ultraviolet solar radiation. Since the summer of 1996, ESA has routinely produced 3-day global measurements of total ozone and nitrogen dioxide using GOME data, and later this was expanded with the launch of Scanning Imaging Absorption Spectrometer for Atmospheric Cartography (SCIAMACHY) on Envisat in 2002, which looks at reflected solar radiation not only at nadir but also at the Earth's limb.

The Ozone Monitoring Instrument (OMI) was developed in the Netherlands and launched aboard NASA's Aura satellite in 2004. This instrument now provides enhanced capability for monitoring the global distribution of total ozone on a daily basis, as well as the global distributions of other atmospheric trace gases such as sulfur dioxide and nitrogen dioxide.

As recently as 1998, both TOMS and GOME data show that at its Austral spring low, Antarctic ozone concentrations had worsened to 60% less than early 1970s levels. Today there is some evidence that levels of chlorine in the stratosphere are leveling off. Is this a scientific success story in the making? Will stratospheric ozone concentrations return to pre-1970s levels as the abundance of stratospheric chlorine stabilizes? Only time and continued monitoring will tell.

The Chemistry of Earth's Atmosphere

Some satellite sensors allow scientists to determine the chemical content of the Earth's upper atmosphere using a technique called 'solar occultation,' in which a sensor is pointed toward the horizon at sunrise and sunset to measure the profile of the stratosphere and mesosphere about 30 times per day. In this way sensors, such as the Stratospheric Aerosol and Gas Experiment (SAGE), can determine the presence and abundance of gases and particulates by measuring precisely the visible and ultraviolet wavelengths that are absorbed within the upper atmosphere. Since the spectra of ozone, nitrogen dioxide, sulfur dioxide, and certain aerosols are well-known, scientists can directly correlate SAGE's readings with the presence of these substances within the stratosphere. The solar occultation technique is particularly effective because the sensor is self-calibrating – each occultation event looks directly at the unattenuated sun outside the Earth's atmosphere just prior to sunset or just following sunrise. These observations are then compared to observations of the sun obtained by looking through the atmosphere. The direct sun observations establish an ongoing baseline of the sensor's performance. Adapted from the Stratospheric Aerosol Mission (SAM II) that flew aboard Nimbus-7, the SAGE sensor is essentially a modified sunphotometer. This kind of sensor first flew in 1979 aboard NASA's

Figure 5 Chlorine monoxide (left) and ozone concentration (right) derived by MLS on Aura at approximately 18-km altitude on 11 February 2005 in the Northern Hemisphere (top) and 16 September 2004 in the Southern Hemisphere (bottom). The white lines demark the approximate edge of the winter polar vortex in each hemisphere. The high chlorine monoxide within the polar vortex in the left-hand figures (reds and dark purple shades) is directly associated with, and leads to, a reduced ozone concentration shown in the right-hand figures (which is especially striking in the Southern Hemisphere).

Applications Explorer Mission-2 (AEM-2). A subsequent version of SAGE (SAGE II) was launched aboard ERBS in 1984 and performed well throughout 2001, thus giving scientists a 17-year continuous dataset of upper atmosphere profile measurements. An enhanced version of SAGE (SAGE III) was launched aboard Russia's Meteor-3M spacecraft in 2001 and operated until 2006.

In 1991, NASA launched the Upper Atmosphere Research Satellite (UARS) with a payload of 10 sensors for measuring a wide array of chemical and physical phenomena in the stratosphere and mesosphere (the layers of the atmosphere from approximately 12–80 km in altitude). Not only did UARS extend scientists' ability to monitor stratospheric ozone concentrations into the 1990s but it also provided the first comprehensive picture of the photochemical processes involved in ozone destruction. The UARS Microwave Limb Sounder (MLS) demonstrated that there is a direct link between the presence of chlorine and the formation of chlorine monoxide during winter in the Northern and Southern Hemispheres, and the destruction of ozone. This capability has been further enhanced with the MLS onboard the Aura satellite, which was launched in 2004 (Figure 5).

Among the four instruments carried on the Aura satellite is the OMI instrument that is a nadir-viewing solar backscatter spectrometer used to derive column ozone, nitrogen dioxide, bromine monoxide, chlorine dioxide, sulfur dioxide, formaldehyde, and

aerosols. Nitrogen dioxide was first measured from space by GOME on ERS-2, and is also measured by SCIAMACHY on Envisat. Nitrogen oxides are formed from both natural (lightning, wildfires, and soil emissions) and anthropogenic (power plants, internal combustion engines, fertilizer applications, and agricultural burning) processes, and they have a relatively short lifetime (about a day) and are therefore concentrated near their sources. Because they are short-lived gases in the atmosphere, they show a markedly lower level of concentration during 'weekends' than 'weekdays,' where the 'weekend' is Sunday in Europe, North America, and Japan, Saturday in Israel, and Friday in the Islamic cities of the Middle East. Using data from OMI, GOME, and SCIAMACHY, it is also possible to see the lower level of NO₂ emissions in the Ohio River Valley of the United States due to greater controls on cars and power plants, in contrast to emissions from China that are continually increasing (Figure 6).

A Canadian instrument launched in 1999 aboard NASA's Terra satellite uses gas correlation spectroscopy to determine the abundance of methane and CO in the troposphere. The Measurements of Pollution in the Troposphere (MOPITT) sensor measures emitted and reflected radiation from the Earth in three spectral bands. As this light enters the sensor, it passes along two different paths through onboard containers of CO and methane. The different paths absorb different amounts of energy, leading to small differences in the resulting signals that

Figure 6 Nitrogen dioxide in the troposphere in the United States (top) and Europe (bottom) during 2006 derived by OMI on Aura. The principal sources of NO_2 occur over large populated regions, heavily industrialized areas, and power plants.

directly correlate with the presence of these gases in the atmosphere. Both methane and CO are by-products of burning vegetation as well as fossil fuels. Scientific interest in CO is twofold: the gas controls atmospheric concentrations of oxidants, thus affecting the ability of the atmosphere to clean itself from the ongoing generation of harmful tropospheric ozone from biomass burning and urban smog. Also, through chemical reactions within the lower atmosphere, CO contributes to the production of harmful ozone. MOPITT is helping scientists identify the main sources of these gases as well as improve four-dimensional models of their transport through the atmosphere.

NASA's Aqua satellite carries the Atmospheric Infrared Sounder that was originally designed to measure atmospheric temperature and water vapor throughout the troposphere and up to about 32 km in altitude, using a hyperspectral thermal emission spectrometer. The emission of radiation in the $15\text{-}\mu\text{m}$ wavelength region is strongly influenced by the concentration of carbon dioxide (CO_2) in the Earth's atmosphere, and this signature has been used to derive the concentration of CO_2 in the mid-troposphere. Results show that CO_2 is not as well-mixed as previously believed, and that its transport around the

globe is strongly influenced by mid-latitude jet streams as well as synoptic weather patterns, especially in the Southern Hemisphere (Figure 7).

Where Storm Clouds Gather

Rain clouds form when moisture-laden air is driven skyward by warm updrafts emitted from a sun-warmed land or ocean surface; or when mountain slopes push moist air aloft; or when a wedge of colder, denser air plows warmer, moist air upward to higher elevations. Because cold air cannot hold as much water vapor as warm air, and because the atmosphere cools at higher elevations, water vapor condenses readily into liquid droplet or ice crystal form, in the presence of seed aerosol particles. Were there no aerosol particles in the Earth's atmosphere, there would be no fog, no clouds, no mist, and probably no rain. When water evaporates at the surface, it absorbs energy from its surroundings and stores it as 'latent heat.' When water vapor condenses back into liquid or ice form, it releases its latent heat into its surroundings. Only about 25% of the energy contained within the atmosphere comes directly from

Mid-tropospheric (8 km) Carbon dioxide

Figure 7 Carbon dioxide in the free troposphere (~ 8 km) during July 2003 derived by Atmospheric Infrared Sounder on Aqua. There is a belt of mid-tropospheric air enriched with carbon dioxide that encircles the globe in the mid-latitudes of both hemispheres, due in large part to the mid-latitude jet streams.

January 2010

July 2010

Figure 8 Global monthly averaged rainfall measured by TMI on TRMM on January 2010 (top) and July 2010 (bottom).

the sun's rays; the remaining 75% comes from the release of latent heat contained in water vapor. Most atmospheric water vapor originates from the tropical oceans, where it rises high into the atmosphere to form towering thunderheads. Encircling

the globe along the equator is an almost continuous band of thunderheads known as the Intertropical Convergence Zone, producing roughly three-quarters of the energy in our atmosphere that helps to drive its circulation patterns.

We cannot measure the latent heat contained within clouds. We can, however, measure tropical rainfall. If we are to more accurately determine how much energy our atmosphere receives from latent heat, then we must more accurately measure rainfall. In 1997, NASDA and NASA jointly developed and launched the TRMM into a mid-inclination (35°) precessing orbit. Scientists estimate about 60% of our world's precipitation falls within the band spanning between 30° north and south of the equator. TRMM carries two instruments designed to measure rainfall – the Precipitation Radar (PR) and the TRMM Microwave Imager (TMI). Designed and built by NASDA, the PR is the first satellite sensor to provide three-dimensional images of the internal structures of storm clouds. Its measurements show scientists the intensity and distribution of rain within a storm, the total height of a storm, and the elevation at which ice crystals melt into raindrops. Most importantly, the PR can measure rain rates as accurately as 0.7 mm h^{-1} . While scientists expected to use ground-based Doppler Radar stations to validate TRMM's PR measurements, much to their pleasant surprise they found that the latter exceeds most ground-based measurements in accuracy and spatial resolution.

The TMI is a 'passive' sensor designed to measure minute amounts of microwave energy emitted by the Earth's surface and from within its atmosphere. (Whereas 'active' sensors send pulses of energy and then measure how much gets absorbed and reflected by the target, 'passive' sensors receive and measure only energy originating from, or reflected by, external sources.) These measurements allow TMI to quantify the amount of water vapor, cloud water, and rainfall intensity within the atmosphere. Based on the design heritage of the Defense Meteorological Satellite Program's Special Sensor Microwave or Imager, the TMI has a wider viewing swath (780 km) and finer spectral resolution than its predecessors. TRMM shows that there is a band of heavy rain along the equator that moves north and south of the equator, leading to several months of near-daily rain followed by months of dryness. The Asian monsoon brings rain to China, Southeast Asia, and India between April and September, and South America goes through a rainy season from October through May (Figure 8).

Conclusion

As the preceding sections demonstrate, the Earth's atmosphere changes both physically and chemically over a range of scales of time and space. The atmosphere's chemical makeup affects its physical state, such as its radiative properties. Much like a venetian blind, the gases and particles in the atmosphere selectively absorb and reflect certain wavelengths of solar radiation while allowing others to pass through relatively unhindered. In turn, physical processes in the atmosphere also help determine its chemical makeup. There was growing consensus through the 1970s and 1980s among Earth scientists that we need to take a more holistic approach to global climate change studies. Scientists recognized that nature does not compartmentalize climate phenomena into discreet disciplines and therefore we need to examine the variables of change as integral parts of the vast, interconnected web of cause-and-effect that is Earth's climate system. In short, it is not enough to identify where and when changes occur; we need to understand how and why the mechanisms of change work. Satellite remote sensors offer the only viable means of conducting a comprehensive examination of our planet.

Surface Wind and Stress

WT Liu, California Institute of Technology, Pasadena, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

The basics of scatterometry and air–sea turbulence transfer are discussed to bring out the capabilities of space sensors in measuring ocean surface stress and wind vectors. The scientific significance of wind and stress are described. Past knowledge of stress characteristics was based on those of wind, because of the lack of stress measurements. Using the unique measurement of stress by the scatterometer, the differences between stress and wind over oceanfronts and in hurricanes are revealed. Wind speed retrieval from measurements of radar altimeter, microwave radiometer, and synthetic aperture radar is summarized. Potential improvements in measuring wind and stress are suggested.

Introduction

Wind is air in motion, and it is a vector quantity with a magnitude (speed) and a direction. Sailors understand both the importance and the difficulty in getting information on wind over oceans. Textbooks still describe global ocean wind distribution in sailors' terms: the calms of the doldrums and horse latitudes, the steady trade winds, and the ferocity of the roaring forties. These features are clearly visible in [Figure 1](#), which is derived from one day of observations by a space-based scatterometer, QuikSCAT. Just a few decades ago, almost all ocean wind measurements came from merchant ships. However, the quality and geographical distribution of these wind reports were uneven. Today, operational numerical weather prediction (NWP) also gives us wind information, but NWP depends on models, which are limited by our knowledge of the physical processes and the availability of data.

The ocean interacts with the atmosphere in nonlinear ways; processes at one scale affect processes at other scales. Adequate wind coverage could be achieved only from the vantage point of space. Space-based microwave radars measure ocean surface roughness day and night, under clear and cloudy conditions. Ocean surface roughness is driven by stress, the turbulent transfer of momentum between the ocean and the atmosphere. Stress is another vector quantity closely related to wind. The microwave scatterometer is the best-established instrument to measure surface stress magnitude and direction, and has been promoted as a wind sensor. The scientific significance of wind and stress is introduced in the Scientific Significance section. The principles of the scatterometer are summarized in the Scatterometry section.

The primary functions of the radar altimeter, the synthetic aperture radar (SAR), and the microwave radiometer are not wind measurement, but they give wind speed as a secondary product. Wind speed, even without direction, is important, and wind speed from these sensors can be applied with directional information derived from other means. The space-based polarimetric radiometer also shows sensitivity to wind direction under favorable conditions. These instruments are described in the Other Sensors section.

While the general public knows and feels the wind, very few people know what stress is. Even for oceanographers, the concept of stress distribution is largely derived from that of wind, because there was no large-scale measurement of stress

over the ocean until the launch of the first scatterometer. The relation and the difference between wind and stress are discussed in the Relations between Wind and Stress section. Potential improvements in space-based measurements of wind and stress are given in the Potential Improvements and Conclusion section.

Scientific Significance

Ocean wind is strongly needed for marine weather forecasting and to avoid shipping hazards. Surface wind convergence brings moisture and latent heat that drive deep convection and fuel marine storms. The significance of wind measurement is clearly felt, for example, when a hurricane suddenly intensifies and changes course, or when the unexpected delay of monsoon brings drought. Detailed distribution of wind power is also needed for the optimal deployment of floating wind farms on the open sea that are enabled by new technology.

For oceanographers, it is stress more than wind that drives ocean circulation. The two-dimensional stress field is needed to compute the divergence and curl (vorticity) that control the vertical mixing. The mixing brings short-term momentum and heat trapped in the surface mixed layer into the deep ocean, where they are stored over time. It also brings nutrients and carbon stored in the deep ocean to the surface, where there is sufficient light for photosynthesis. The horizontal currents, driven in part by stress, distribute the stored heat and carbon in the ocean. Stress affects the turbulent transfer of heat, moisture, and gases between the ocean and the atmosphere and is critical in understanding and predicting weather and climate changes.

Scatterometry

During the Second World War, marine radar operators observed noises on their radar screens, which obscured small boats and low-flying aircraft. They termed this noise 'sea clutter'. This clutter was the backscatter of the radar pulses by the small waves on the ocean's surface. The radar operators at that time were quite annoyed by these noises, not knowing that, a few decades later, scientists would make important applications with them.

Figure 1 Over the ocean, white streamlines indicating wind direction are superimposed on the color image of U_N at 00Z on 6 August 1999, derived from objective interpolation of the observations by QuikSCAT. Normalized backscatter coefficients measured by the same instrument over land and Antarctica are also displayed.

The scatterometer sends microwave pulses to the Earth's surface and measures the power backscattered from the surface roughness. The roughness may describe the characteristics of polar ice or vegetation over land. Over the ocean, which covers nearly three-quarters of the earth's surface, the surface roughness is largely due to the small centimeter waves on the surface. These surface waves are believed to be in equilibrium with the local stress. The backscatter depends on not only the magnitude of the stress but also the stress direction relative to the direction of the radar beam (azimuth angle). The capability of measuring both stress magnitude and direction is the major unique characteristic of the scatterometer.

At incident angles greater than 20° , the radar return is governed by Bragg scattering, and the backscatter increases with stress. The backscatter is governed by the in-phase reflections from surface waves. The geophysical model functions (GMF), from which ocean surface wind and stress are retrieved from the observed backscatter, in the form of the normalized radar cross-section (σ_o), are largely based on empirical fits of

data. The symmetry of backscatter with wind direction requires observations at many azimuth angles to resolve the directional ambiguity. Because of uncertainties in the wind retrieval algorithm and noise in the backscatter measurements, the problem of directional ambiguity was not entirely eliminated even with three azimuthal looks in the scatterometers launched after SEASAT (in 1978). A median filter iteration technique has been commonly used to remove the directional ambiguity.

Because there is much more wind information than stress information and the public is more familiar with wind than stress, an equivalent neutral wind (U_N) is used as the geophysical product of the scatterometer. By definition, U_N is uniquely related to stress, while the relation between stress and the actual wind depends on atmospheric stability (see [Relations between Wind and Stress](#) section). Although scatterometers have been known to measure surface stress, they have been used and promoted as wind-measuring instruments, and U_N has been used as the actual wind, particularly in operational

weather applications. More explanation is given in the Relations between Wind and Stress section.

Over the large expanse of ocean, which is quasi-stationary and horizontally homogeneous under near-neutral conditions, and where ocean surface current is negligible, U_N may be the same as the actual wind. Over the sharp horizontal current shear and temperature gradients of oceanfronts, however, stress variation could be very different from that of winds. The observation of the rotation of scatterometer measurement in opposition to the surface current, in the meanders of the Kuroshio Extension current, is a clear characteristic of turbulent stress generated by shear. One would expect wind to be dragged in the same direction as the current, but stress is the vector difference between wind and current, and the direction would be deflected from the current. Figure 2 clearly shows that where the vorticity of U_N measured by QuikSCAT is positive, the vorticity of the surface current measured by the drifters is negative and vice versa, indicating opposite rotations.

The ubiquitous spatial coherence between sea surface temperature (T_s) and U_N , measured by the scatterometer and

found under a variety of atmospheric conditions, is also characteristic of turbulent stress generated by buoyancy. In the unstable region, atmospheric buoyancy generates turbulent momentum transport and increases the stress magnitude. Figure 3(a) shows the coherence over the Kuroshio Extension. Figure 3(b) shows similar coherence between T_s and U_N computed from a uniform wind field under similar stability conditions, demonstrating that the coherence is a characteristic of stress and not wind. Factors affecting larger-scale wind, such as the pressure gradient force, the Coriolis force, and baroclinicity, are not important at the small scales of turbulence, and that is the reason for ubiquitous coherence. The higher stress over warmer water affects atmospheric wind aloft, but the influence will be subjected to these large-scale factors. Ocean parameters, such as surface current and temperature, are needed to derive wind from stress in these frontal regions.

Retrieving strong winds from the scatterometer is also difficult. The problem is obvious in Figure 4, which is derived from NASA's scatterometer on QuikSCAT measuring at the Ku-band (14 GHz). Data for the 12 hurricanes in the North

Figure 2 (a) Filtered vector (black arrows) superimposed on vorticity (color, 10^{-6} s^{-1}) of U_N observed by QuikSCAT, averaged from June 2002 to May 2005. (b) Filtered vector (black arrows) superimposed on vorticity (color, 10^{-6} s^{-1}) of the surface current measured by Lagrangian drifters, averaged from 2000 to 2004. The large-scale gradients are removed by a two-dimensional filter.

Figure 3 (a) Isotherms of filtered T_s measured by the Advanced Microwave Scanning Radiometer for EOS (AMSR-E; EOS is NASA's Earth Observing System) (0.2°C interval) superimposed on (a) filtered magnitude of QuikSCAT U_N (color, m s^{-1}); and (b) filtered U_N computed from a uniform wind field of $u = 7.5 \text{ m s}^{-1}$ (color, m s^{-1}), averaged from June 2002 to May 2005. Solid and broken lines represent positive and negative values, respectively. The same filter as in Figure 2 is applied.

Atlantic in the 2005 season, excluding those with over 10% chances of rain, were examined. Figure 4 shows that, in moderate winds ($U < 35 \text{ m s}^{-1}$), the logarithm of σ_o (in db) increases linearly with the logarithm of wind speed at both polarizations. At strong winds ($U > 35 \text{ m s}^{-1}$), however, σ_o increases at a much slower rate with increasing wind speed. Similar saturation is found in the European Advanced Scatterometer (ASCAT), measuring at the C-band (5 GHz). Such high wind saturation has also been observed from aircraft flying over hurricanes.

When the model function developed over the moderate wind range is applied to the strong winds, an underestimation of wind speed results. Strong efforts have been made to adjust the model function (slope in Figure 4) in strong winds and to find the right channel (a combination of polarization, frequency, and incident angle) that would be sensitive to the increase of strong winds. The success would be difficult if flow separation occurs at high winds and the surface roughness and stress do not increase with winds, as discussed in the Relations between Wind and Stress section.

Other Sensors

Both the microwave altimeter and SAR are similar to the scatterometer in the sense that they are active sensors that send microwave pulses to the Earth's surface and measure the backscattered power. The microwave radiometer is a passive sensor, observing the radiance from the Earth and its atmosphere.

While the scatterometer views at oblique angles, the altimeter views at nadir (very small incident angles). At nadir, the backscattered energy is a result of specular reflection (the wavelets serve as small mirrors), and the backscatter is not sensitive to the U_N direction. Because the instrument is not scanning, data are available only at very narrow (2 km) repeated ground tracks. The coverage of all the past altimeters is poor compared with the scatterometer and the microwave radiometers.

A SAR looks perpendicular to the aircraft path at only one azimuth angle, and cannot resolve the U_N direction like the scatterometer. SAR has spatial resolutions that are much better

Figure 4 Normalized radar cross-section at two polarizations measured by QuikSCAT for 12 hurricanes as a function of collocated surface wind provided by the National Hurricane Center.

than those of scatterometers, but the high resolution also introduces higher uncertainties in accuracy caused by secondary effects that affect surface roughness. The instrument and the data-processing procedure are much more complicated than those of the scatterometer, and there have been serious calibration problems. The scatterometer GMF can be used to relate the σ_o measured by SAR to U_N . However, a particular value of σ_o may correspond to a range of U_N , depending on the azimuth angle. Hence, in order to retrieve U_N with the GMF, the U_N direction must first be specified. Whether the a priori direction information is derived from the orientation of kilometer-scale structure in the SAR image, or from operational NWP models, the spatial scales are much coarser than σ_o .

Ocean surface wind speed has also been derived from the radiance observed by a microwave radiometer. It is generally believed that wind speed affects the surface emissivity indirectly through the generation of ocean waves and foam. Radiometers are designed to observe how the ocean surface operates

primarily at window frequencies, where atmospheric absorption is low. Radiances at frequencies sensitive to sea surface temperature, atmospheric water vapor, and liquid water are also measured; they are used to correct for the slight interference by the atmosphere. It was demonstrated in several airborne experiments that the polarization properties of the sea surface emission vary not only as a function of the wind speed, but also as a function of wind direction. Wind direction-measuring capability has been evaluated for a polarimetric radiometer, WindSat, launched by the US Navy.

Relations between Wind and Stress

Ocean surface stress (τ) is the turbulent transfer of momentum generated by atmospheric instability caused by both wind shear (difference between wind and current) and buoyancy (vertical density stratification resulting from temperature and

humidity gradients). Direct τ measurement has been done in only a few field campaigns in the past. For all practical purposes, our knowledge of τ is derived from winds (U) at a reference height through a drag coefficient C_D , which is defined by

$$\tau = \rho C_D (U - U_s)^2 \quad [1]$$

where U_s is the surface current and ρ is the air density.

The drag coefficient C_D has been derived largely in field campaigns. **Figure 5** illustrates the behavior of C_D at neutral stability. At low wind speed ($U < 3 \text{ m s}^{-1}$), the flow is smooth; C_D increases with decreasing wind speed. And at moderate wind $3 < U < 20 \text{ m s}^{-1}$, C_D is an increasing function of wind speed for a rough sea with open fetch. Secondary factors, such as sea states and spray from breaking waves, whose data are not generally available, are not included in this parameterization scheme and should be part of the errors.

In a similar fashion, the turbulent fluxes of heat H and moisture E have been related to the mean parameters – wind speed U , potential temperature T , specific humidity Q at 10 m, sea surface temperature T_s , and the interfacial humidity Q_s (usually taken to be the saturation humidity at T_s), which are the measurements generally available from routine ship reports, through

$$H = \rho c_p C_H (T - T_s)(U - U_s) \quad [2]$$

$$E = \rho C_E (Q - Q_s)(U - U_s) \quad [3]$$

where c_p is the isobaric specific heat.

In the past, the transfer coefficients, C_H and C_E , were approximated with the same values as C_D . W.T. Liu first postulated in 1979 that, in a rough sea, under a moderate range of winds ($5\text{--}20 \text{ m s}^{-1}$), C_H and C_E do not increase with wind speed because of molecular constraint at the interface, while C_D may still increase because momentum is transported by form drag. Liu's hypothesis, as illustrated in **Figure 5**, was subsequently supported by measurements in field experiments. K. Emanuel argued in 1995, from theoretical and numerical model results, that Liu's hypothesis could not hold at the strong wind regime of a hurricane. To attain the wind strength of a hurricane, the energy dissipated by drag could not keep increasing while the energy fed by sensible and latent heat does not increase with wind speed. His argument puts limits on the increase of C_D as a function of wind speed. The postulation of

the level of the increase of C_D with wind speed at hurricane-scale winds was supported by the results of the laboratory studies and the aircraft experiments. Such flow separation may explain the saturation of scatterometer measurements at wind speeds higher than about 32 m s^{-1} , as shown in **Figure 4**.

The drag coefficient, or the bulk parameterization of stress, can be expressed as the nondimensional flux–profile relation (also called the similarity function) in the constant flux layer.

$$\frac{U - U_s}{U_*} = 2.5 \left(\ln \frac{z}{z_0} - \psi_U \right) = \frac{1}{\sqrt{C_D}} \quad [4]$$

where $U_* = (\tau/\rho)^{1/2}$ is the frictional velocity, z_0 is the roughness length, and ψ_U is a function of the stability parameter, which is the ratio of buoyancy to shear production of turbulence. Typical wind profiles at various stabilities are shown in **Figure 6**. From the zero intercept and the slope of the logarithm profile, z_0 and U_* can be determined. In general oceanographic applications, the surface current is assumed to be small compared with wind and the atmosphere is assumed to be nearly neutral. Neglecting U_s and ψ_U in eqn [4], U becomes U_N , and it is uniquely related to U_* (or τ). To compute U_N from conventional wind measurements of U (A on the blue curve in **Figure 6**), U_* and z_0 are computed as the slope and intercept at the surface of the curve in **Figure 6**. The neutral relation (straight line) defined by U_* and z_0 will give U_N (point B). This method has been used in the development and calibration of all scatterometers launched by NASA. At a given level, U_N is greater than the actual wind (U) under unstable conditions but lower under stable conditions. From eqn [4], $U_N - U = 2.5 U_* \psi_U$, assuming z_0 depends much stronger on wind shear than buoyancy and this difference is the inherent error of using scatterometer measurements as the actual wind. The formulation of ψ_U was largely based on experiment data on land, validated with only a small amount of measurement over ocean, and may have considerable uncertainties.

Potential Improvements and Conclusion

Historically, the European Space Agency used the C-band (5 GHz), but NASA prefers the Ku-band (14 GHz) in their scatterometers. The backscatter at higher frequencies is more sensitive to shorter ocean waves. The Ku-band is more sensitive

Figure 5 Variation of the bulk transfer coefficients of momentum (drag coefficient), heat, and moisture with wind speed by Liu et al. (1979).

Figure 6 Typical wind profiles at various stability conditions derived from the flux–profile relation by Liu et al. (1979). B is the equivalent neutral wind corresponding to the actual wind measurement at A.

to weak wind–stress variations but is more subjective toward atmospheric effects and rain contamination. Wind retrieval at the L-band (1 GHz) has also been attempted because L-band backscatter is not sensitive to atmosphere and rain attenuation. There have been calls for a multifrequency scatterometer that is sensitive to various parts of the ocean surface wave spectrum and may reduce atmospheric and rain effects.

Present scatterometers are real-aperture systems, and the spatial resolution is limited by the antenna size. A larger antenna will, of course, enhance the spatial resolution. Another way to achieve higher resolution is to add synthetic aperture capability.

One of the drawbacks of present scatterometers is the ambiguity in retrieving wind–stress direction. The backscatter is a cosine function of the azimuth angle. In a recent experiment, it was demonstrated that the correlation between copolarized and cross-polarized backscatter of radiance is a sine function of the azimuth angle. By adding polarized measurement capabilities to the scatterometer, the directional ambiguity problem could be mitigated.

One polar-orbiting scatterometer at a low-altitude (e.g., 800 km) orbit can sample at a location on Earth not more than two times a day. Additional instrument flying in tandem will allow descriptions of higher temporal variability and the reduction of the aliasing (bias introduced by subsampling) of the mean wind–stress.

Not all space-based ocean surface wind and stress measurements are comparable in quality. Standardizing the technology requirements for observation accuracy with different research and operational applications and for international cooperation is very desirable. Many scientific reports have affirmed the need for high-quality, continuous, and consistent long time series of ocean surface vector winds and stress.

Temperature Soundings

Synopsis

Atmospheric temperature can be derived from satellite measurements using a variety of viewing geometries and wavelengths, exploiting emission, absorption or scattering processes which depend directly on temperature or indirectly via atmospheric density.

Operational temperature sounders, flown since the 1970s, are nadir-viewing instruments which sense thermally emitted radiation in the infrared or microwave regions and use the spectral variation of atmospheric absorption to sound different depths. Limb-viewing allows profile information to be obtained directly from the viewing geometry but also requires the simultaneous retrieval of pressure. Occultation instruments usually measure density profiles from which temperature can be inferred.

Introduction

Temperature plays a key role in radiative, dynamical, and chemical processes in the atmosphere. However, compared to most other parameters, atmospheric temperature has a relatively low variability: typically ± 20 K, or about $\pm 10\%$ of the absolute value, at any altitude (Figure 1). This low variability imposes correspondingly tight constraints on the useful accuracy of any measurements. Nevertheless, remote sounding has now developed to the point where temperature can be retrieved with accuracies of 2 K or better, comparable with the quality of measurements made *in situ* using radiosondes. The main impetus for this development has come from the meteorological community: although radiosondes provide good coverage over populated land areas, accurate weather forecasting requires global temperature fields, which can only be obtained from satellites.

'Operational' temperature sounders have been flown on the NOAA series of polar orbiting satellites since 1972 (augmented since 2006 by the European MetOp satellites and eventually to be superseded by the JPSS satellites). These are nadir viewing instruments, measuring emission in the infrared and microwave regions of the spectrum. By selecting channels sensitive to

emissions from different depths into the atmosphere the vertical temperature structure can be determined. Nowadays, the more sophisticated forecast models assimilate directly the satellite radiance measurements themselves, bypassing the need for any explicit temperature profile retrieval.

Temperature can also be retrieved using emission measurements from the atmospheric limb, i.e., viewing the atmosphere tangentially rather than vertically. Limb sounding allows temperature to be retrieved to higher altitudes and with improved vertical resolution compared to nadir sounding, but at the expense of reduced horizontal resolution and signal-to-noise ratio. A third possibility for temperature sounding is solar occultation: viewing the Sun as it rises or sets beyond the atmospheric limb and determining temperature through its effect on the atmospheric absorption.

Such measurements all rely on modeling molecular absorption spectra, which largely determine radiative transfer at infrared and microwave wavelengths. However, since temperature and density are linked via the hydrostatic equation, the temperature profile may also be inferred from measurements which are more directly related to the atmospheric density profile, such as scattering in visible and UV wavelengths, or refraction at radio frequencies. Molecular (Rayleigh) scattering is routinely used to determine atmospheric temperature from ground-based lidars, and atmospheric composition from space, but has had only limited application in temperature sounding from space. Radio occultation techniques for determining density via refraction were originally developed for sounding the atmospheres of other planets; however, the GPS network of navigational satellites is now also used to provide routine temperature soundings of the Earth's atmosphere.

Physical Mechanisms

Atmospheric temperature and density affect electromagnetic radiation through absorption, emission, refraction, and scattering. All of these mechanisms can be exploited in order to retrieve temperature using remote sensing techniques.

Thermal Radiation

Most techniques for temperature sounding rely on measurements of thermally emitted radiation in either the infrared or

Figure 1 Typical atmospheric temperature profiles for midlatitude (green), equatorial (red), and polar winter (blue) conditions.

microwave region of the spectrum. The monochromatic radiance, I , from a line of sight through a nonscattering atmosphere in local thermodynamic equilibrium (LTE) can be represented by

$$I = \int_{\infty}^0 B \frac{d\tau}{ds} ds + I_{\infty} \tau_{\infty} \quad [1]$$

where B is the Planck function, τ the transmittance from space to a point at distance s along the path, and τ_{∞} represents the attenuation of any emission source I_{∞} beyond the atmosphere. The atmospheric contribution to this radiance is therefore a spatially weighted average of the Planck function along the path, $d\tau/ds$ being the 'weighting function.' Since B is a known function of temperature and wavelength, determining $B(T(s))$ from the above relationship is equivalent to retrieving the temperature profile. However, to use eqn [1] it is also necessary to know the transmittance $\tau(s)$ along the path, conveniently expressed in terms of an optical thickness χ :

$$\tau = \exp(-\chi) \quad [2]$$

$$\chi = \int_0^s \nu \sigma \rho ds \quad [3]$$

where ν is the absorber volume mixing ratio, ρ is the (molar) air density, and σ is the absorption coefficient ($\text{m}^2 \text{mol}^{-1}$).

At thermal wavelengths, σ is a function of the concentrations of various absorbing species, pressure and temperature. Composition ν can be eliminated as an unknown by selecting spectral regions where the absorption is primarily from a well-mixed species, usually the $15 \mu\text{m}$ CO_2 band in the infrared or the 60 GHz O_2 band in the microwave. Pressure is either implicit in the retrieval coordinates (nadir sounding) or retrieved simultaneously with temperature (limb sounding).

Planck Function

The Planck function (Figure 2) is given by:

$$B = \frac{2hc^2}{\lambda^5 (\exp(hc/\lambda kT) - 1)} \quad [4]$$

where h is Planck's constant, c is the speed of light, k is Boltzmann's constant, λ is the wavelength, and T is the temperature. This has a maximum at $\lambda_{\text{max}} = 2.9 \times 10^{-3}/T \text{ m}$ (Wien's displacement law), which for typical atmospheric temperatures lies between 10 and $15 \mu\text{m}$. The curve falls off as $1/\lambda^4$ at longer wavelengths, and as $\exp(-hc/\lambda kT)$ at shorter wavelengths. The rapid decay at short wavelengths means that thermal emission is negligible below a few microns and, in any case, below $4 \mu\text{m}$ scattered or reflected solar radiation becomes significant during the daytime.

The accuracy of a temperature retrieval depends not only on the radiance signal-to-noise ratio (SNR) but also on the sensitivity of radiance to temperature, dB/dT , which reduces with increasing wavelength. At $10 \mu\text{m}$, $B \approx T^6$ but in the microwave region ($1\text{--}10 \text{ mm}$ wavelengths) $B \propto T$ (in fact, 'radiance' and 'temperature' are often used interchangeably when referring to microwave measurements). For a given SNR, this means that temperature can be retrieved more accurately at shorter wavelengths. Conversely, this also means that at shorter wavelengths retrievals of other species are more sensitive to any given

Figure 2 Red and blue lines show the Planck function evaluated at 300 and 200 K, representing the typical range of atmospheric temperatures. The orange line shows the Planck function for 5800 K, scaled to give an integrated irradiance of 1370 W m^{-2} (solar constant) representing the maximum diffuse solar contribution. The green line (right axis) shows the sensitivity n fitting $B \sim T^n$, evaluated at $T = 240 \text{ K}$. The wavenumber axis (top) is proportional to frequency, 1 cm^{-1} corresponding to approximately 30 GHz .

temperature error. For example, a number of constituents (H_2O , CH_4 , N_2O , NO_2) are often retrieved using bands in the $6\text{--}8 \mu\text{m}$ region. At these wavelengths, a 1 K temperature overestimate results in a 4% increase in predicted radiance, and therefore a roughly equivalent underestimate in retrieved concentrations. Hence the need for accurate temperature retrievals for all remote sensing experiments based on infrared emission.

Molecular Absorption

The molecules of many atmospheric species exhibit absorption bands at infrared wavelengths corresponding to transitions between quantized vibrational energy levels (molecules of nitrogen and oxygen being notable exceptions, having no permanent electric dipole moment). Superimposed on these vibrational states are rotational states which have a finer quantization. Changes in vibrational level are often accompanied by changes in the rotational quantum number J , giving the typical band structure shown in Figure 3. The central peak (Q-branch) corresponds to a pure vibrational transition ($\Delta J = 0$), and the envelope of lines at lower (P-branch) and higher (R-branch) wavenumbers correspond to $\Delta J = \pm 1$, the spread in these envelopes reflecting the rotational energy dependence $E_R \approx J(J+1)$. Pure rotational transitions also occur, leading to absorption features in the microwave spectrum (Figure 4).

The overall strength of a particular absorption band is determined by the population of the two vibrational levels involved. In LTE, populations of each vibrational energy level E_V follow the Boltzmann distribution $\sim \exp(-E_V/kT)$. For $T = 240 \text{ K}$, $kT \ll E_V$ (167 cm^{-1} compared to $\sim 1000 \text{ cm}^{-1}$) so usually only 'fundamental' transitions between the ground state and the first excited level are significant.

Figure 3 Top: The absorption coefficient σ of the CO_2 15 μm fundamental ν_2 vibration band at 10 hPa total pressure, 240 K, displaying the P, Q, and R branches. Bottom: The change $\Delta\sigma$ resulting from a 10 K increase in temperature. (The atmospheric CO_2 column amount is around 130 mol m^{-2} .)

Figure 4 The absorption coefficient σ of the O_2 rotational band at 60 GHz, 1000 hPa (red), and 100 hPa (blue). (The atmospheric O_2 column amount is around $7.3 \times 10^4 \text{ mol m}^{-2}$.)

The shape of an absorption band, given by the envelope encompassing the P and R branches, depends on the population distribution over the rotational energy levels E_R . This also follows Boltzmann statistics but here $kT \gg E_R$. The additional degeneracy factor $(J + 1)$, representing the increased number of states available at higher rotational quantum numbers, ensures that the most probable rotational quantum number is not $J = 0$ but some higher number, and increases with increasing temperature (indicated by the outward displacement of the peaks of the P- and R-branches in Figure 3).

As well as the line strength and the shape of bands, the temperature–pressure profile also affects the width of individual lines through Doppler broadening (high altitudes) and pressure broadening (low altitudes, Figure 4).

The above assumes LTE, i.e., that the populations of the vibrational and rotational energy levels are characterized by the same temperature as the mean kinetic energy. In practice, this means that collisions between molecules occur sufficiently frequently to ensure that the internal energy levels are redistributed according to the local kinetic temperature. At high altitudes, other processes may dominate leading to nonthermal population distributions of the vibrational states (so-called ‘non-LTE’ effects). These often limit the upper altitude of practical infrared retrieval schemes. Non-LTE effects are usually negligible in the microwave region due to the small energy difference between rotational levels; instead, when sounding the mid-stratosphere or higher altitudes, complications are introduced by having to model the Zeeman splitting of lines in the Earth’s magnetic field.

Hydrostatic Equation

In most situations, the profiles of atmospheric pressure p , molar density ρ , and temperature T can be assumed to be in hydrostatic balance:

$$dp = -gM\rho dz \quad [5]$$

$$\frac{dp}{p} = -\frac{gM}{RT} dz \quad [6]$$

where g is the gravitational acceleration, M the molar weight of air, R the gas constant, and z the altitude.

In addition to retrieving temperature, it is usually necessary to know the pressure in order to evaluate terms in eqn [3], although absolute altitude is not critical. If $T(p)$ is retrieved directly (e.g., nadir sounding) this is not a problem and eqn [6] can be integrated to obtain layer thicknesses Δz . If $p(z)$ is retrieved (e.g., microwave limb sounding), eqn [6] can be used to obtain temperature. If $T(z)$ is retrieved (e.g., infrared limb sounding), it is also necessary to retrieve pressure at least at one altitude, $p(z_{\text{ref}})$, and obtain $p(z)$ by integrating eqn [6]. If $\rho(z)$ is retrieved (e.g., radio occultation, limb scattering), it may be adequate to assume some climatological pressure at high altitude and integrate eqn [5] downward to obtain $p(z)$, hence $T(z)$, with any error δp in the climatological assumption decreasing in significance further down the profile.

Refraction

The speed of electromagnetic radiation is reduced in air due to the polarizability of air molecules. The refractive index n is conveniently expressed in terms of a refractivity $N = n - 1$, which is usually assumed to be proportional to air density. For dry air at 15 °C and standard pressure, Edlén’s dispersion relation models the wavelength dependence of refractivity from 0.2 to 2 μm (Figure 5):

$$N \times 10^6 = 64.328 + \frac{29498.1}{146 - \mu^{-2}} + \frac{255.4}{41 - \mu^{-2}} \quad [7]$$

Figure 5 Variation of refractivity (red, left axis) and Rayleigh scattering cross section (blue, right axis) in the visible and near-infrared region of the spectrum. The scattering extinction is scaled to the number of molecules in a vertical column of atmosphere.

where μ is the wavelength expressed in μm . For wavelengths longer than $1 \mu\text{m}$, refractivity is essentially independent of wavelength and approaches a value of 2.73×10^{-4} . However, at radio frequencies ($<20 \text{ GHz}$) the dipole moment of water vapor has a significant effect, which can be modeled as:

$$N \times 10^6 = 77.6 \frac{(p - e)}{T} + 3.73 \times 10^5 \frac{e}{T^2} \quad [8]$$

where p and e are the total pressure and partial pressure of water vapor in hectopascals, respectively, and T is the temperature in Kelvin. At 15°C and standard pressure, this gives values of refractivity varying from $N = 2.73 \times 10^{-4}$ for dry air (i.e., the long wavelength limit of eqn [7]) to $N = 3.41 \times 10^{-4}$ for saturated air (1.6% water vapor by volume).

Refraction introduces a curvature into limb paths, lowering the tangent point and increasing the path-integrated air mass compared with the straight-line path. For a circularly symmetric atmosphere, it can be shown that the tangent height correction is:

$$\delta z \approx Na \quad [9]$$

where a is the radius of the Earth. For a tangent height of 25 km , $\delta z \approx 70 \text{ m}$ for infrared wavelengths, equivalent to a 1% increase in the tangent point pressure and a similar increase in integrated air mass. Since the effect is proportional to density ($\propto N$), it doubles for every $\sim 5 \text{ km}$ decrease in tangent height.

Scattering

For visible and shorter wavelengths, 'Rayleigh' scattering by air molecules becomes significant. The Rayleigh scattering cross section σ_{Ra} ($\text{m}^2 \text{mol}^{-1}$; cf. σ in eqn [3]) can be computed theoretically:

$$\sigma_{Ra} = \frac{32\pi^3}{3N_A \rho^2 \lambda^4} N^2 \quad [10]$$

where N_A is Avogadro's number. Since refractivity $N \propto \rho$, the Rayleigh scattering cross section per mole of air depends only on wavelength, through the $1/\lambda^4$ term (Figure 5).

For optically thin paths, single scattering can be assumed so that measurements of extinction or scattered radiation can be simply related to the air density. However, this assumption breaks down at higher pressures, when multiple scattering and/or Mie scattering (by particles of radius comparable to the wavelength, e.g., aerosols) have to be considered.

Nadir Sounding

The earliest satellite temperature sounders viewed downward, measuring the radiance emerging from the top of the atmosphere in a range of spectral bands. The different transmission characteristics of each band can be used to derive information on temperature from different optical depths into the atmosphere. This is still the basis of most of the operational temperature sounders used today.

Weighting Functions

Adapting eqn [1], the radiance I emerging from the top of the atmosphere above a nonreflective surface is given by:

$$I = B_0 \tau_0 + \int_0^\infty B \frac{d\tau}{dZ} dZ \quad [11]$$

where $Z = -\ln(p/p_0)$ is a heightlike coordinate, and subscript 0 indicates surface values. For nadir viewing, it is convenient to use a pressure-based coordinate such as Z since the transmittance, and therefore weighting functions are themselves mostly pressure dependent.

Using the hydrostatic equation (eqn [5]) to adapt eqn [3] to pressure coordinates, the optical depth χ from space to pressure level p for a well-mixed absorber with volume mixing ratio v and constant absorption coefficient σ is given by:

$$\chi = \int_p^0 \frac{v\sigma}{g} dp = \alpha p \quad [12]$$

where $\alpha = v\sigma/g$ is a constant. The weighting function is then given by:

$$\frac{d\tau}{dZ} = -p \frac{d\tau}{dp} = \alpha p \exp(-\alpha p) \quad [13]$$

It can be shown that this has a maximum where the optical depth $\chi = \alpha p = 1$ and a width at half maximum of $\Delta Z \approx 2.5$ scale heights ($\sim 15 \text{ km}$).

By suitable placement of filters within the band it is possible to select weighting functions peaking at different pressures (Figures 6 and 7).

Vertical Resolution

From eqn [13] and Figure 7, it can be seen that the width of nadir sounding weighting functions is comparable with the thickness of the entire troposphere. The weighting function width does not fundamentally limit the vertical resolution of the retrieval, but the large overlap means that in order to retrieve a profile at, say, seven levels corresponding to the weighting function peaks, most of the information will come from the difference between radiance measurements in adjacent channels rather than from the absolute values, hence reducing the effective SNR.

Figure 6 The CO₂ 15 μm absorption band showing the pressure level for which optical depth = 1 (i.e., from which transmittance to the top of the atmosphere is e^{-1}). The spectrum is averaged over 1 cm⁻¹ intervals. Also shown are the positions of HIRS/3 channels 1–7 (see Figure 7).

Figure 7 Solid lines: the weighting functions for HIRS/3 channels 1–7 (see Figure 6). These are normalized so that the maximum atmospheric contribution is 1. Also plotted (dotted lines) are the equivalent weighting functions for channels of width 1 cm⁻¹.

To produce narrower weighting functions requires finding spectral regions where the optical depth χ increases more rapidly with pressure than $\chi \propto p$ (eqn [12]). One method is to select spectral regions where emission is predominantly from the wings of pressure-broadened lines (giving $\sigma \propto p$, hence $\chi \propto p^2$). Another method is to target emission from a gas whose concentration increases with pressure, such as tropospheric water vapor. Since the absorber is no longer well mixed, additional channels are required in order to retrieve its concentration, and the weighting function peaks are no longer at fixed pressures.

A different method of improving the vertical resolution is to scan at an angle θ to nadir, increasing the optical path to approximately $\chi = \alpha p \sec \theta$, reducing both the peak pressure

and width by a factor $\cos \theta$. Taken to its extreme, this is, of course, the basis of limb sounding. Scanning to $\pm 50^\circ$ across the orbit track is commonly employed for nadir sounders, but this is done in order to cover the atmosphere between adjacent orbit tracks, and a ‘correction’ applied in order to remove the resulting variation of the weighting functions.

Nadir Sounding Instruments

Table 1 lists nadir viewing instruments that have been used for temperature sounding. The first such instruments were infrared filter radiometers targeting various parts of the CO₂ 15 μm band, a simple technique which is still in use on operational satellites (Figure 6). However, such filters are limited to a minimum width of several wavenumbers which does not allow much scope for improving vertical resolution or extending coverage to higher altitudes.

More recently, instruments have been developed to measure the full infrared spectrum at high resolution: 1 cm⁻¹ for AIRS (grating spectrometer), 0.5 cm⁻¹ for IASI (interferometer), and 0.1 cm⁻¹ for TES (interferometer, in nadir viewing mode). As illustrated in Figure 7, the weighting functions associated with these narrower channels are not significantly different in shape to those of High-Resolution Infrared Radiation Sounder (HIRS). In principle, the high resolution allows selection of spectral regions with pressure-broadened line wings and/or water vapor lines for a joint retrieval with temperature, but the main improvement in vertical resolution is achieved simply by combining a much larger ($\sim$ hundreds) number of channels.

Figure 6 suggests that 4 hPa is about the highest level that can be sounded using the 15 μm band with 1 cm⁻¹ resolution. However, Figure 8 demonstrates that emissions can be detected from higher levels, but in order to discriminate these it is necessary to resolve individual lines. Doppler-broadened line widths at the stratopause are of the order of 0.001 cm⁻¹, well beyond the resolution obtainable using spaceborne interferometry, and even were such a resolution attainable the reduced photon flux from such a narrow bandwidth would lead to SNR problems.

Gas correlation radiometry is one technique which has been used to extend the altitude range of infrared nadir sounding. By passing the signal through a pressure-modulated cell of CO₂ a synchronous component of the signal can be extracted corresponding to emission in just the modulated regions of the cell transmittance spectrum. The mean cell pressure determines the region of the atmosphere being sounded by this modulated component. Since this also integrates the signal over all lines within the filter band, it gives an improved SNR compared to a single narrow bandwidth measurement. This was the principle used in the Stratospheric Sounding Unit (SSU) that provided the stratospheric sounding channels for the TIROS Operational Vertical Sounder (TOVS) instruments.

The main advantage of sounding in the microwave rather than infrared region is that clouds are transparent at millimeter wavelengths. Spectral selection for microwave instruments is achieved by radio, rather than optical, techniques. Heterodyne mixing is used to combine the atmospheric microwave signal with a local oscillator (LO) at some central frequency ($\sim$ GHz). Since the mixing process is nonlinear, an ‘intermediate frequency’ ($\sim$ MHz) signal is produced

Figure 8 Atmospheric radiance spectrum (nadir view) calculated near the center of the CO₂ 15 μm band. The smooth envelope around 220 K corresponds to emission from the pressure-broadened line wings in the lower stratosphere (Figure 1), the upward spikes from Doppler-broadened lines at the stratopause (260 K), and the downward spikes from centers of strong lines near the mesopause (190 K).

corresponding to the difference between the two input signals. The result is to convert the atmospheric spectrum immediately above the LO frequency from microwave to radio frequencies, with the mirror image of the atmospheric spectrum below the LO frequency also superimposed. The spectral features can then be resolved with radio frequency filters. The technology has now developed to the point where it is possible to achieve adequate SNR in bandwidths comparable to a stratospheric line width, allowing sounding up to the stratopause (Figures 9 and 10).

Operational Temperature Sounders

The National Oceanic and Atmospheric Administration (NOAA) began routine atmospheric temperature sounding measurements (Table 2) with the Vertical Temperature Profile Radiometer (VTPR) instruments on board the NOAA 2–5 satellites which operated from 1972 to 1979. These were infrared radiometers with six temperature sounding channels from 13 to 15 μm, plus a water vapor channel at 18 μm, and another channel in the 11 μm atmospheric window.

The VTPR was superseded by the TOVS suite, first flown on the TIROS-N satellite in 1978 and subsequently on the NOAA 6–14 satellites. TOVS consisted of three instruments:

- HIRS/2, a development of the HIRS instrument originally flown on Nimbus 6. This was a 20-channel infrared radiometer with 12 temperature sounding channels covering

Figure 9 The O₂ 60 GHz absorption band (upper) showing the pressure at which the optical depth equals 1, and (lower) a close-up of the region around the AMSU/A 57.29 GHz LO frequency (marked by the dashed line). Also shown are the positions of AMSU/A channels 3–14. Note the use of both sidebands for channels 5 and 10, and four-sideband combinations for channels 11–14, distributed about combinations of two LO frequencies (57.29 ± 0.32 GHz, marked by dotted lines). This superimposes similar spectral features into the intermediate frequency signal in order to improve the SNR. The resulting weighting functions are shown in **Figure 10**.

both the 15 μm and the 4.3 μm CO₂ bands, in addition to water vapor, ozone, and atmospheric windows.

- SSU, a development of the Pressure Modulated Radiometer (PMR) instrument also flown on Nimbus 6. This measured CO₂ emission at 669 cm^{-1} using three different pressure modulator cells (at 1.5, 5, and 15 hPa) for stratospheric temperature sounding.
- Microwave Sounding Unit (MSU), a four-channel microwave radiometer sounding the O₂ band at 60 GHz.

Advanced TOVS (ATOVS) was first flown on NOAA-15, launched in 1998, and consists of two instruments:

- HIRS/3, a 20-channel infrared radiometer with similar spectral channels to HIRS/2 (**Figures 6 and 7**). HIRS/4, with improved spatial resolution, was flown on NOAA-18 and NOAA-19.

Figure 10 The AMSU/A weighting functions for channels 2–14 (channel 2 lies at 31.4 GHz, see **Figure 9** for the other channels). These are normalized so that the maximum atmospheric contribution is 1.

- Advanced Microwave Sounding Unit (AMSU), a 20-channel microwave radiometer designed for temperature and water vapor sounding (**Figures 9 and 10**). This replaced the MSU and SSU with a single microwave instrument.

Under the original Polar Operational Environmental Satellites (POES) program, NOAA aimed to maintain operational satellites in two different Sun-synchronous polar orbits: one with a southward Equator crossing at around 7.30 a.m. local time (AM orbit) and one with a northward Equator crossing at around 2.30 p.m. (PM orbit) so that coverage of any point is repeated every 6 h.

With the launch of Metop-A in 2006 (Table 1), the European Organisation for the Exploitation of Meteorological Satellites (EUMETSAT) took over responsibility for the AM orbit. This satellite, the first of three, contains both HIRS/4 and AMSU instruments (for continuity) as well as new instruments for temperature sounding: the infrared Fourier-transform spectrometer, IASI, and a GPS receiver GRAS.

After NOAA-19 (launched in 2009) the USA had planned to merge the NOAA and military DMSP programs into the National Polar orbiting Operational Environmental Satellite System (NPOESS). This led to the development of the interim NPP (NPOESS Preparatory Project) satellite, launched in October 2011 and renamed Suomi NPP. However, the NPOESS project has subsequently been abandoned and the NOAA component will continue with the Joint Polar Satellite System (JPSS) satellites in the PM orbits, while the military program continues with the Defence Weather Satellite Systems (DWSS) satellites in the AM orbits. The NPP and JPSS-1,2 satellites contain two new instruments for temperature sounding: Cross-track Infrared Sounder (CrIS), an infrared Fourier-transform spectrometer similar to IASI; and the Advanced Technology Microwave Sounder (ATMS), which is an improved version of AMSU.

Limb Sounding

Viewing tangentially through the atmospheric limb the background is cold space so that semitransparent optical paths can be used in preference to opaque paths, and consequently the weighting functions are determined by geometry rather than optical thickness. Compared with nadir viewing, limb viewing generally allows better vertical resolution and coverage to higher altitudes. However, a fundamental problem with the limb viewing geometry is that the ray paths traverse significant horizontal distances in the atmosphere (~ 200 km in the 1 km thick layer above the tangent point), which limits the scale of horizontal structures which can be resolved. Also, tropospheric limb views are more likely to be obscured by clouds than nadir views, restricting low altitude coverage using the infrared. For these reasons, limb viewing is particularly suited to temperature sounding in the stratosphere and mesosphere, while nadir sounding is preferred for the troposphere.

For a typical polar orbiting satellite at 700 km altitude, the tangent point is some 3000 km away so that 3 km at the tangent point subtends only 0.001 radians, or approximately 3' of arc. The narrow field of view reduces the radiance flux so that SNR becomes a significant problem. Diffraction is also a limiting factor for microwave instruments: angular resolution varies approximately as the ratio of antenna width to wavelength, so to resolve 0.001 radians at 2 cm (60 GHz) would require a 5 m antenna.

Weighting Functions

Neglecting the background term due to cold space, eqn [1] becomes:

$$I = \int_{-\infty}^{\infty} B \frac{d\tau}{dx} dx \quad [14]$$

where x is now the distance along the tangent path, with $x = 0$ at the tangent point and $x \approx \pm\infty$ at the satellite. Ignoring

refraction and assuming a spherical Earth of radius a , distance x , and altitude z ($\ll a$) along a path are related by

$$x^2 \approx 2a(z - z_t) \quad [15]$$

where z_t is the altitude of the tangent point. For an isothermal atmosphere at temperature T , the molar density of air, ρ , varies with altitude as:

$$\rho = \frac{p_t}{RT} \exp\left(-\frac{z - z_t}{H}\right) \quad [16]$$

where p_t is the pressure at the tangent point, and $H (=RT/gM)$, from eqn [6] the atmospheric scale height. Integrating eqn [3] along the path, assuming constant absorber volume mixing ratio ν and absorption coefficient σ , and converting to altitude coordinate $z' = z - z_t$:

$$\chi = \nu\sigma \int_{-\infty}^{\infty} \rho dx \quad [17]$$

$$= \nu\sigma \frac{p_t}{RT} \sqrt{2a} \int_0^{\infty} \frac{1}{\sqrt{z'}} \exp\left(-\frac{z'}{H}\right) dz' \quad [18]$$

$$= \nu\sigma \frac{p_t}{RT} \sqrt{2\pi aH} \quad [19]$$

If the absorption is weak then $I \approx B\chi$ and $d\tau/dz \sim -d\chi/dz$ so the characteristic shape of limb viewing weighting functions is given by:

$$\frac{d\tau}{dz} \propto \frac{1}{\sqrt{z'}} \exp\left(-\frac{z'}{H}\right) \quad [20]$$

In practice, the width of the peak is limited by the layering assumed for the retrieval. Examples, converted to temperature ($dI/dT(z)$ rather than $dI/dB(z)$), are plotted in Figure 11. Note

Figure 11 Temperature weighting functions for a limb viewing instrument using a 610–640 cm^{-1} filter (HIRDLS channel 3, see Figure 13). Curves show radiance response at altitudes indicated by the vertical axis to a 1 K temperature perturbation at the labeled tangent heights.

that at lower altitudes, where this spectral region becomes opaque, the weighting functions resemble those of a nadir sounder (Figure 7).

The vertical profile can be sounded either using a single detector and scanning in elevation, or by using a detector array to view the different elevation angles simultaneously. However, in practice, at least two spectral channels are required in order to retrieve pressure profile information as well.

Pressure Determination

To model the atmospheric transmittance (eqn [14]), it is also necessary to know the pressure, which is usually retrieved simultaneously with temperature (the problem does not arise in nadir sounding since the equivalent radiative transfer equation, eqn [11], is formulated in pressure coordinates). This requires radiance measurements in at least two spectral channels with different pressure–temperature characteristics.

Differences in temperature sensitivity arise from the spectral dependence of the Planck function or variations in the absorption coefficient, e.g., the changing shape of the rotational band structure (Figure 3). Some variation in pressure sensitivity may also arise from the absorption coefficient, but the biggest effect is the nonlinear variation of radiance with optical thickness: $I \approx B(1 - \exp(-\chi))$ (from eqn [14]), with $\chi \propto p$ (eqn [19]).

Figure 12 illustrates the problem graphically, with good pressure–temperature discrimination corresponding to conditions where radiance contours from any two channels intersect at a large angle. At high pressure, all radiances are independent of tangent point pressure ($I \approx B$, opaque limit). At low pressure, all radiances vary linearly with pressure ($I \approx \chi$, transparent limit). The best pressure–temperature discrimination occurs between 100 and 10 hPa (15–35 km in the atmosphere) as the channels undergo different transitions from the opaque to transparent limits.

Figure 12 Radiance contours for the four HIRDLS CO₂ channels (Figure 13) for a range of pressures and temperatures simulating different tangent point conditions. The black line shows the $T(p)$ profile of the US Standard atmosphere.

Figure 13 Absorption (1-transmittance) spectra for limb paths through different tangent heights across the CO₂ 15 μm band. Also shown are the spectral positions of the four HIRDLS temperature sounding channels (channels 2–5, see also Figure 12).

For spectrally resolving instruments such as MIPAS, it is usually possible to find optically thin spectral regions where the different temperature sensitivity of line strengths can be exploited to discriminate between tangent point temperature and pressure variations (Figure 14).

For microwave measurements, radiances can be almost independent of temperature. Assuming $I \approx B\chi$ (optically thin), and considering only the pressure- and temperature-dependent components of eqn [19]:

$$I \propto B\sigma \frac{p}{T} \sqrt{H} \quad [21]$$

For the wings of Lorentz-broadened lines, $\sigma \propto p/\sqrt{T}$, and since the scale height H and, in the microwave region, B are both proportional to T , the temperature dependences all cancel out, leaving $I \propto p^2$.

Since it is generally not possible to retrieve both temperature and pressure independently over all altitudes, it is usual to include some knowledge of the vertical distance between tangent points, either using the fixed geometry of a detector array or else pointing information from the elevation scan, and assume hydrostatic balance (eqn [6]) to constrain the problem.

Limb Emission Sounders

Table 3 lists limb emission instruments used for temperature retrievals. The various techniques for nadir viewing instruments all have their parallels in limb sounding, although with modifications driven by the different viewing geometry.

As with nadir sounding, the earliest measurements were made with infrared radiometers using the CO₂ 15 μm band. The good SNR performance achievable with broad filters means that this technique continues to be used for high spatial resolution measurements (Figure 13). Although the precise choice of filter position does not have as crucial an influence on the sounding characteristics as in the nadir viewing case, it is nevertheless desirable to choose spectral regions of intermediate absorption. Too opaque and little information is

Figure 14 Upper: Absorption (1-transmittance) spectra for limb paths through different tangent heights within the CO₂ 15 μm band viewed with the MIPAS resolution of 0.0625 cm⁻¹ (the plotted region is around 13.5 μm in wavelength). Lower: The variation in the radiance (in units of nW cm⁻² sr⁻¹ (cm⁻¹)⁻¹) from 40 km tangent height with changes in the tangent point pressure and temperature. Note the change in response between 738 and 742 cm⁻¹, which can be used to discriminate between the pressure and temperature effects.

obtained from the tangent point, too transparent and the SNR is unnecessarily reduced. Apart from requiring at least two channels in order to retrieve both pressure and temperature, additional channels can be used in order to optimize the transmission characteristics for different altitude ranges.

Gas correlation and spectrally resolving instruments are usually employed in limb sounding in order to discriminate between lines of the target molecule and those of other species. However, foreign lines have only a small influence in the 15 μm CO₂ band so, for temperature sounding, the main advantage of these instruments is in improving the pressure–temperature discrimination. The main drawback is the reduced SNR associated with the narrower bandwidth and, in the case of gas correlation, the need to view perpendicularly to the orbital motion in order to avoid introducing Doppler shifts between the atmospheric lines and those in the onboard cell.

Microwave instruments have an advantage over infrared instruments in being insensitive to cloud at low altitude and to non-LTE effects at high altitude. However, vertical resolution is limited by diffraction, which can cause problems in resolving the tropopause and, at high altitudes it becomes necessary to model the Zeeman splitting of lines which varies with the Earth's magnetic field along the line of sight. Since the radiances are almost independent of temperature, these instruments effectively retrieve a pressure profile, with temperature information coming mostly from hydrostatic balance. Concomitantly, the impact of any temperature errors on the constituent retrievals is also reduced.

These measurements all rely on thermal emission from the atmosphere, but, at shorter wavelengths, Rayleigh-scattered sunlight can also be detected. Since the scattering is proportional to air density, measurements of the scattering profile can be used

to determine the temperature profile. The technique is only usable during daytime, and for relatively high altitudes where Rayleigh single scattering can be assumed, but has been used with SME and OSIRIS measurements (both grating spectrometers).

Occultation Measurements

Occultation measurements use the Sun, the Moon, or the Stars as the source of the detected radiation and monitor the change as the source rises or sets beyond the atmospheric limb (GPS occultation is discussed in a separate article). While the geometry is the same as that of limb emission measurements, the location of the tangent point is defined by ephemeris data (i.e., knowledge of the positions of the satellite, the Earth, and the source), which is usually more accurate than using the satellite attitude/pointing data which defines the tangent point for limb emission measurements. Potentially, occultation retrievals can therefore be performed on an absolute height scale. However, the relative motion of the source often means that the locus of tangent points is far from vertical, leading to 'slanted' profiles, extending over several hundred kilometers horizontally. Apart from the practical difficulties in using such profiles, the assumption of hydrostatic balance also becomes less valid.

Table 4 lists the instruments used for occultation measurements of temperature.

Solar Occultation

The Sun can be viewed through the atmospheric limb as a satellite passes between the day and night hemispheres, i.e., twice an orbit, or about 30 times in 24 h for a polar orbiting satellite.

Solar radiation, equivalent to that of a 5800 K blackbody, has a peak at visible wavelengths (Figure 2) but for temperature–pressure sounding it is necessary to use molecular features in the near-infrared such as the O₂ A-band at 0.76 μm or the CO₂ bands at 2.7 and 4.3 μm . With the Sun in the line of sight, thermal emissions from the atmosphere are negligible, so eqn [1] can be simply integrated:

$$I = B_{\text{sun}} \tau \quad [22]$$

Taking the ratio with the high-altitude radiance $I_{\text{sun}} = B_{\text{sun}}$ gives the atmospheric transmittance τ , with weighting functions $d\tau/dz$ as for limb sounding (eqn [20]).

The main advantage of solar occultation over limb emission measurements is the high SNR, allowing increased vertical and spectral resolutions, and sounding to higher altitudes. Also, since the measurements are of transmittance rather than emission, non-LTE effects are generally less significant and, by taking the ratio of radiances, the measurements are self-calibrating.

Since the absolute altitude of the tangent point is known (in practice this depends on the ability of the solar tracker to keep locked on to the same part of the solar disk), it is possible to retrieve temperature using only a single channel. Pressure information at the lowest altitude $p(z)$ obtained from meteorological fields and integrated upward.

Alternatively, transmittance spectra can be acquired at high spectral resolution using an interferometer (with the Sun as the source, SNR is less of a limitation on resolution than for emission measurements). As with limb emission measurements, spectral regions can usually be found where the pressure and temperature signatures can be distinguished, for example as shown in Figure 15.

Comparing this with the equivalent emission signatures in Figure 14, note that the temperature sensitivity is reduced relative to the pressure sensitivity since there is no significant atmospheric contribution from the Planck function (integral term in eqn [1]). In this particular example the pressure–temperature discrimination arises from the rotational structure of the R branch of a CO₂ transition, with the line strength (hence pressure sensitivity) decreasing toward higher wavenumbers, while the temperature sensitivity increases (Figure 3).

At shorter wavelengths, it is possible to determine the temperature profile (via air density) by measuring the attenuation due to Rayleigh scattering. This has been applied to SAGE II data, but measurements of molecular absorption are generally preferred.

Whichever technique is used, the main disadvantage of solar occultation is that only around 30 profiles a day can be obtained, with the sunrise and sunset profiles confined to two narrow latitude bands and no information obtainable during nighttime or the polar winter. In principle, the number of measurements could be doubled by including lunar occultation (which would also allow measurements other than at local sunrise–sunset times) but this has not been applied in practice. One instrument, GOMOS (primarily designed for high-altitude ozone measurements), uses stellar occultation: observing any

Introduction

The measurement of water vapor from space now has an extensive history going back to 1978, when the NASA Nimbus 7 spacecraft was launched carrying two sensors, the Limb Infrared Monitor of the Stratosphere (LIMS), and the Stratospheric and Mesospheric Sounder (SAMS). Both carried channels at 6 μm wavelength in the infrared, to detect thermal emissions from the atmosphere as the spacecraft orbited the Earth in a polar orbit. Shortly afterward, a new generation of operational meteorological sounders was launched by National Oceanic and Atmospheric Administration (NOAA), also in the United States, carrying the TIROS Operational Vertical Sounder (TOVS) package; part of TOVS was the High Resolution Infrared Sounder (HIRS), which made measurements of water vapor in the troposphere. Since that time satellite instruments operating in the infrared, the visible, and the microwave regions of the electromagnetic spectrum have operated in space, and a long series of measurements in both troposphere and stratosphere have been made. This article reviews these measurements.

Principles and Overview

In this section, we discuss some of the general principles involved in remote sensing of atmospheric constituents, before we present some specific examples of satellite missions which have measured atmospheric water vapor.

Emission or Absorption

Remote sensing operates by detection of electromagnetic (e.m.) radiation from the Earth by an instrument on an orbiting spacecraft. There are two principal sources of e.m. radiation that have been most widely used in measurements of water vapor to date. These are the thermal emission from water molecules, and absorption of the visible/near ultraviolet radiation from the Sun. There are other techniques that could be mentioned, such as measurement of solar scattering, or the use of artificial radiation sources, such as lasers, but since these have not been used very widely for water vapor measurements, we will not consider them further in this article.

Thermal Emission

The Planck radiation law describes the maximum thermal radiation that can be emitted as a function of wavelength from any object at a temperature, T . This law shows that the intensity of radiation is a smooth curve with a single maximum at a wavelength in the infrared, λ_m , defined by Wien's displacement law

$$\lambda_m T = 2898 \mu\text{m K} \quad [1]$$

where the wavelength is expressed in microns, μm . Therefore, as an example, at a temperature of $T = 250 \text{ K}$ (which is a typical temperature in the midtroposphere), the maximum intensity occurs at about 11.6 μm . In practice, the intensity of radiation is also dependent on the optical thickness of the atmospheric path under consideration: this, in turn, depends on the density or concentration of the absorbing molecules along that path. If this is written in terms of the Planck function, $B(\lambda, T)$, and the density of water vapor as a function of height, $\rho_w(z)$, then

$$I(\lambda, \theta) = \int_z^{z_t} B(\lambda, T(z)) \tau(z, z_t) \alpha_\lambda \rho_w(z) f(\theta) dz \quad [2]$$

where α_λ is the absorption coefficient expressing the strength of electromagnetic coupling to the radiation field at wavelength λ , $\tau(z, z_t) = \exp(-\int_z^{z_t} \alpha_\lambda \rho_w(z) f(\theta) dz)$ is the transmittance from z to z_t (the top of the atmosphere), and $f(\theta)$ allows for non-vertical transmission paths ($=1/\cos \theta$ for $\theta < \sim 60^\circ$). If the temperature of the atmosphere is known from other measurements, then the dependence of $I(\lambda, \theta)$ on $\tau(z, z_t)$ and $\rho_w(z)$ allows density to be determined.

Absorption

In the absorption case, the controlling equation, say for the case of looking at the Sun through the atmosphere at the limb of the atmosphere, is

$$I(\lambda, \theta) = I_0(\lambda) \tau(z_g, z_t) \quad [3]$$

where z_g is the grazing height, or the minimum height of the solar beam as it traverses the atmosphere, and $\tau(z_g, z_t)$ represents the transmittance of the path from the edge of the atmosphere on the sunward side, via the grazing height, and on to the edge of the atmosphere on the satellite side. Knowing the extraatmospheric solar intensity, $I_0(\lambda)$, allows the transmittance and therefore the density to be determined. The principal differences from emission sensing are that absorption does not depend (at least to first order) on atmospheric temperature, and that emission measurements may be made at any time of day or night, whereas solar-dependent methods can obviously be applied only when the Sun is in the right location.

Limb or Nadir Sounding

We have already indicated that the direction in which we view the atmosphere is important. There are two principal techniques in use. In the first, nadir sounding, widely used for sounding the lower atmosphere or troposphere, the satellite sensor is directed toward the nadir, i.e., downward

from the spacecraft. This is used most, often in emission mode, and the upwelling thermal radiation from the atmosphere is observed. It proves possible to detect emission from broad but distinguishable layers of the atmosphere because the term known as the ‘weighting function,’ $W(z)$, defined as

$$W(z) = \frac{d\tau}{dz} = \tau(z, z_t) \alpha_{\lambda} \rho_w(z) f(\theta) dz \quad [4]$$

displays a single peak at a height dependent on the values of the separate terms, which can be arranged to be at heights between the surface and the tropopause. Because of this property, the density of water vapor in the troposphere can be sounded as a function of height. The technique of nadir sounding using atmospheric emission is used widely in meteorological sounding, including the measurement of humidity.

In limb sounding, the limb of the atmosphere, just above the horizon, is viewed with a sensor with a narrow field of view. Either emission or solar absorption may be employed. By geometrically limiting the field of view, the vertical profile of emission or absorption, and therefore the vertical profile of water vapor density, may be scanned.

Choice of Wavelength

In principle, any wavelength at which there is thermal emission or solar absorption, and at which the water vapor in the atmosphere is spectrally active, may be employed. In practice, thermal emission from the infrared bands or microwave bands of water vapor have been used most frequently for the detection of atmospheric humidity.

Summary of Missions and Instruments

We have space here to only review a relatively few examples of satellite remote sensing of water vapor. Table 1 lists some of the more successful attempts to do so, organized into the three categories of infrared emission, microwave emission, and infrared and visible solar absorption (occultation).

Examples of Satellite Experiments to Measure Water Vapor in the Atmosphere

Infrared Thermal Emission Measurements

Troposphere

The principal satellite instrument for measuring tropospheric water vapor over the past few decades has been the HIRS, one of the suite of instruments making up the TOVS package. ‘TIROS’ in this nested acronym stands for the Television and Infra Red Operational Sounder, the original name for the NOAA weather monitoring system. HIRS is an infrared sounder, viewing the upwelling radiation from the atmosphere below the spacecraft. HIRS has 20 channels, formed using interference pass-band filters, throughout the thermal infrared, including three that measure around $6.3 \mu\text{m}$ wavelength in the ν_2 emission band of water vapor. The ‘footprint’ or spatial resolution of HIRS is about 25 km in the nadir, and about 40 km at each end of the sideways scan that it uses to maximize coverage. Table 2 gives some of the important parameters of channel 12 of HIRS, which detects upper-tropospheric water vapor.

The upwelling IR radiation comes from a restricted range of altitudes, defined by the strength of water vapor absorption at each wavelength. This idea is captured by the definition of the weighting function, $W(z)$, introduced above, which measures the relative amount of radiant energy reaching the spacecraft flying above the atmosphere from each layer within the atmosphere. $W(z)$ is actually equal to the vertical derivative of transmittance at the wavelength in question, as shown in eqn [4]. An example of the typical shape of the HIRS 12 weighting function is shown in Figure 1. At wavelengths where the spectral absorption coefficient is larger, the curve shown is higher in the atmosphere, and vice versa for a wavelength at which the absorption coefficient is smaller.

In order to develop a qualitative understanding of the shape of the weighting function, and how its height depends on absorption coefficient, consider the following. From the highest layers of the atmosphere, the density of water vapor is very low, so that the emission signal reaching our spacecraft instrument is very low from these layers. If we imagine moving deeper into the atmosphere, the emission signal seen at the

Table 1 Satellite instrument for measurement of water vapor: a sample

Calibration	Onboard black body and cold space view

spacecraft increases, as the density of water vapor increases. At some point, defined by the magnitude of the absorption coefficient at the wavelength in question, another effect begins to come into play: because the emitting layers are now overlain by quite a lot of absorbing water vapor, the IR radiation emitted from these layers toward space is actually partly absorbed before it emerges from the top of the atmosphere. Moving deeper still into the atmosphere means that this reabsorption effect increases, until, for the deepest layers

(depending on the absorption coefficient, and therefore the wavelength), the energy actually reaching the top of the atmosphere can fall to near zero. Hence, the general shape of the weighting function. If the wavelength is changed to a more absorbing one, the height of the peak in $W(z)$ rises, and vice versa. In this way, though with modest vertical resolution, the water vapor density of the troposphere can be mapped in three dimensions as the satellite orbits over the greater part of the globe.

Data from HIRS/TOVS have been available since 1979, with minimal gaps, and provide an important source of information about the distribution and variability of water vapor in the troposphere, used by scientists interested in both short-term weather and long-term climate. Figure 2 illustrates some data from HIRS.

An instrument called MOPITT (Measurements of Pollution in the Troposphere) was launched on board the Terra satellite in December 1999, to provide measurements of CO in the troposphere, with relatively coarse vertical resolution, but with good horizontal sampling; these allow maps of CO distribution to be produced, and MOPITT techniques are also usable in principle to measure water vapor. In addition, in 2003 the EOS Aura satellite will carry the TES (Tropospheric Emission Spectrometer) instrument, which will make a variety of very valuable measurements of tropospheric constituents, including water vapor, with excellent spatial and temporal resolution. TES is based on the pedigree established by the Fourier

Figure 1 Examples of weighting functions for HIRS 12 in the TOVS package. The HIRS 12 weighting functions for two different profiles of water vapor, expressed as the precipitable water vapor in the layers 1000–500, 500–300, and 300–100 hPa, are shown, compared with weighting functions for two other instruments, SSM/T2, and GMS-5, a geostationary instrument.

Figure 2 Measurements of upper-tropospheric humidity (UTH) in the layer 500–200 hPa measured by HIRS, expressed as maps for the four seasons DJF, MAM, JJA, and SON, averaged over the years 1980–97.

transform experiment called ATMOS, which flew on the Space Shuttle, to measure the high-resolution spectrum and composition of the stratosphere. Table 3 shows some of the basic characteristics of TES.

Stratosphere

In many ways, the remote sounding of the stratosphere is simpler than that of the troposphere. This is because in the stratosphere there are virtually no clouds to interrupt the line of sight and complicate the observed signal; the densities are lower, so that spectral lines are narrow and better separated than in the troposphere; and techniques like limb sounding may be used, in which the long path to the horizon maximizes the signal from trace molecules, and provides a cold background of space against which to make measurements. These advantages are considerable, and have led to the development of many stratospheric remote sounding techniques, while tropospheric sounding is still in its infancy.

As an example, we take the LIMS, which flew on the Nimbus 7 satellite, and which operated from 25 October 1978 to 28 May 1979. LIMS was a cryogenically cooled broadband filter

radiometer, which included a water vapor channel at $6.9 \mu\text{m}$. The 7-months life was limited, by design, by the lifetime of the solid cryogenics used.

LIMS provided the first comprehensive global view of stratospheric water vapor. The new data were used, along with measurements of CH_4 from the UK SAMS, to study the budget of water vapor and hydrogen in the stratosphere. Precision, or relative accuracy, varied from $\pm 10\%$ for pressures greater than about 10 hPa to 15% between 5 and 10 hPa. Much was learned about the operation and characteristics of an advanced IR sounder during this experiment, experience which was valuable in developing later generations of instruments.

The LIMS experiment has been followed by other IR sensors, employing a variety of techniques, too many to be reviewed fully here. The reader is referred to the survey contained in the book *Earthwatch* listed under Further Reading.

Microwave Thermal Emission Measurements of the Stratosphere

In the extreme far infrared, or microwave region, at wavelengths beyond about 1 mm or so, a fundamental change in techniques is necessary. Thermal radiation is still emitted by all objects, but the intensity is so weak that it may be detected with any certainty only by using the radio techniques of superheterodyne detection. Thus, systems involving mixers and local oscillators (LO) have been developed (the mixers/detectors are related to the old crystal set whistlers) and have been used to detect the sidebands formed by mixing of the incoming signal from the atmosphere with the LO. Such systems have been developed over many years to achieve the high sensitivity in brightness temperature that is necessary to detect emission lines from atmospheric gases such as H_2O , O_3 , CO , ClO , and others.

Table 3 TES characteristics

Maximum sampling time of 16 s with a signal-to-noise ratio of up to 600:1
Limb mode: altitude coverage = 0–34 km
Nadir and limb viewing (fully targetable)
Spectral region: $3.2\text{--}15.4 \mu\text{m}$
Swath: $5.3 \times 8.5 \text{ km}$
Spatial resolution: $0.53 \times 5.3 \text{ km}$
Mass: 385 kg (allocation)
Power: 334 W (allocation)
Date rate: 6.2 Mbps (peak); 4.9 Mbps (average)
Physical size: $140 \times 130 \times 135 \text{ cm}$ (stowed); $304 \times 130 \times 135 \text{ cm}$ (deployed)

Figure 3 (a) Examples of midlatitude water vapor mixing ratios for the period October 1991–April 1993, measured by MLS (version 0104, solid lines) and HALOE (version 19, broken lines). In each case the darker line is the mean and the lighter lines the standard deviation. (b) Differences between MLS and HALOE: solid – mean difference; dotted – r.m.s. difference; dashed – absolute mean difference; dot-dashed – combined instrumental uncertainties.

The principal advantages of the microwave technique are that the spectral resolution of the system is extremely high, so that atmospheric line shapes can be resolved, while at these long wavelengths, scattering due to particles and droplets is small (see the λ^{-4} dependence of Rayleigh scattering on wavelength), so that clouds and dust are less of a problem to remote sounding. Problems can arise in the calibration of such systems, for example, because standing waves are set up in apparatus which can change if a component is physically rotated or moved, and which can give rise to a varying background signal. Also, because of the long wavelength, diffraction limits the field of view that can be achieved, unless very large antennae are used. Nevertheless, very useful measurements have been made, relatively uncontaminated by cloud or dust.

The accuracy quoted for latest version of MLS water vapor measurements is about ± 0.3 ppmv at 20 km, 0.2 ppmv at 40 km, and about 0.5 ppmv at 70 km.

The Microwave Limb Sounder (MLS) which flew on the Upper Atmosphere Research Satellite (UARS) demonstrated the true power of a limb sounding microwave radiometer for making global measurements for the first time. A more advanced instrument is being developed for the NASA EOS Aura mission, and is currently scheduled to be flown in 2003.

Some examples of MLS data, in a comparison with HALOE measurements, are shown in Figure 3.

Solar Occultation Measurements

Solar occultation, uses the Sun as a source of radiation and measures the change in signal as the Sun rises or sets behind the limb of the atmosphere. Solar occultation has been used with great success in a number of experiments. We note the valuable data produced by the Stratospheric Aerosol and Gas Experiment. However, we use as an example the most highly successful stratospheric experiment perhaps of recent times, the Halogen Occultation Experiment (HALOE). This is a thermal IR solar occultation device with a number of spectral channels, which uses gas correlation techniques as well as broadband filters. In gas correlation spectroscopy, a sample of the gas to be detected is carried in a cell on board, and provides a natural filter to atmospheric radiation specifically from that gas. HALOE has worked now for just on 10 years, and has provided

a quite unprecedented set of data on the stratosphere over this long period. Given that more and more scientific interest is coming to be centered on long-term changes in our climate, the continued operation of this extremely valuable instrument is most important.

Among the advantages of this experiment are the well-known ones due to limb sounding (see earlier). In addition, however, the solar occultation method allows an absolute calibration against the Sun outside the atmosphere at each limb scan. This has proven an extremely important advantage when the data have come to be used for long-term trend and variability studies. The main disadvantage of the solar occultation technique is that since the measurement is made only during local sunrise and sunset, only two measurements are made per orbit: for a 15 orbit day, that is 30 observations per day, with a quite widely spaced horizontal sampling (see Figure 4). This

Figure 4 HALOE sampling pattern for the year of 1995. Circles mark the tangent points for sunrise observations, crosses those for sunset observations. The tracks are due to a combination of orbit, season, and the reversal of the spacecraft for thermal balance reasons.

Figure 5 Trends in stratospheric water vapor at levels between 120 and 0.15 hPa for two periods, January 1992–December 1996 (dotted) and January 1992–April 1999 (solid). Bars show standard deviation at each level.

should be compared with the closely spaced, uniform sampling possible from a nadir sounder like HIRS.

HALOE measures not only H_2O but also CH_4 , O_3 , NO , NO_2 , and temperature. The combination of water vapor and methane measured simultaneously by one sensor has been exploited by a number of groups to study the hydrogen budget and water vapor trends of the stratosphere: trends of the order of $50\text{--}150\text{ ppbv year}^{-1}$ occurred during the first half of the 1990s, less in the second half. Such changes produce significant change in the water vapor amount in the stratosphere, which may influence the radiative balance due to this species.

Figure 5 shows an estimate from HALOE data of the trends over the periods January 1992–December 1996 and January 1992–April 1999, demonstrating the change in trends detected over these two periods. These trends are still not well understood, but it has been shown that they have a significant effect on the Earth's radiative energy balance.

Synopsis

Earth's atmosphere has evolved over 4.5 Ga to reach its present state. The atmosphere is subject to myriad influences, both exogenous, like the solar wind and meteoritic impacts, as well as endogenous, such as outgassing and plate tectonics. By studying noble gas isotope ratios and the rock record, we can define how these processes shaped Earth's atmosphere. Life has also played a profound role in Earth's atmospheric history, affecting the content of key constituents such as oxygen, nitrogen, and various greenhouse gases. Based on life's role in the cycling of atmospheric gases, the Gaia hypothesis suggests that the biosphere regulates Earth's climate to sustain suitable conditions for living organisms.

The Diversity of Planetary Atmospheres

Although the planets Mercury, Venus, Earth, and Mars have masses within a single order of magnitude range, they possess atmospheres with extremely different properties (**Table 1**). These bodies may have initially possessed primordial atmospheres of solar composition whose dominant light gases (hydrogen and helium) were lost to space and replaced by

outgassed water, carbon dioxide, and nitrogen (and small amounts of other gases) during the final phase of accretion 4.5 billion years (Ga) ago. The divergence in atmospheric composition seen today may in part reflect differences in initial volatile abundance, but much of the diversity can be attributed to the individual evolutionary paths of these atmospheres over the age of the solar system. Rates of planetary atmospheric evolution have differed markedly. Whereas the other planets have suffered catastrophic atmospheric evolution (Mercury has experienced complete loss, Venus, a runaway greenhouse and devolatilization of surface rocks, and Mars has lost most of its atmosphere to space or its crust), the evolution of Earth's atmosphere has been comparatively mild. Atmospheric evolution is controlled by both external processes such as radiation and the corpuscular wind from the Sun and impacts, and internal processes such as volcanism and recycling of a planet's crust (e.g., plate tectonics). While some processes drive the exchange of compounds between the atmosphere and reservoirs in the surface, oceans, or interiors of planets, or the interconversion of different chemical species, others result in the secular, irreversible evolution of the atmosphere. Examples

Table 1 The atmospheres of the inner planets Mercury, Venus, Earth, and Mars

Planet	Mass (Earths)	Pressure (hPa)	Composition
Mercury	0.053	10^{-9}	H, He, Na
Venus	0.817	90 000	96% CO ₂ , 3% N ₂ , minor CO, SO ₂
Earth	1	1000	78% N ₂ , 21% O ₂ , 1% Ar, minor H ₂ O, CO ₂
Mars	0.107	7	95% CO ₂ , 3% N ₂ , 2% Ar, minor CO, O ₂

of the former include atmospheric photochemistry, volcanism, and plate tectonics. Examples of the latter include the accretion of new material (impacts of comets or meteorites), escape of hydrogen to space, and the sequestration of certain elements (siderophiles) into the metallic core.

Earth's atmosphere has been profoundly affected by another process called life. The modern atmosphere, containing abundant oxygen in gross chemical disequilibrium with surface organic carbon and gases such as methane, is a testament to life's ability to efficiently convert light energy into chemical energy, some of which is stored in the chemical disequilibrium between the atmosphere and surface. Significant disequilibrium is not present on the sterile worlds of Venus and Mars, and it has been suggested that the simultaneous presence of pairs of gases like O₂ and CH₄ in an atmosphere may serve as a planetary 'biosignature' that reveals the presence of life even at a distance. Some gases such as CO₂, the principal source of biological reduced carbon, are maintained at mixing ratios much lower than the level predicted in the absence of life. The current terrestrial atmosphere (Table 2) is far from the end state reached on Venus, where all of the surface volatiles are in the atmosphere. Also in contrast to neighboring planets, the terrestrial atmosphere maintains conditions suitable for life (providing a modest greenhouse effect and a shield against biologically harmful radiation), and has apparently done so for 3.5 Ga, despite a 40% increase in solar luminosity, giant impacts, and the changing tempo of plate tectonics.

Evolutionary Processes

The early atmosphere would have been subjected to frequent bombardment by planetesimals left over from early planetary accretion. These impacts may have brought in volatiles, but they may also have removed (to space) some of the existing atmosphere either by the momentum of the impact shock wave or heating of the upper atmosphere (see below). Impacts also turn over the crust and expose fresh surfaces, accelerating chemical interactions between the atmosphere and crustal rocks. Giant impact basins on the Moon date to 3.9 Gy of age,

indicating that a similar bombardment shaped the Earth's atmosphere for the first several hundred million years of its history.

A second process that may have profoundly (perhaps catastrophically) affected Earth's atmosphere was the formation of the iron–nickel core. This removal of metallic iron (and possible fractions of iron-soluble elements like sulfur, carbon, and hydrogen) left the Earth's surface and mantle in a considerably more oxidized chemical state, a condition that would have been reflected in the oxidation state of the compounds that were being outgassed by volcanoes. Thus, as is the case today, CO₂, N₂, and SO₂ were the dominant components of volcanic gases, rather than CH₄, H₂S, and NH₃.

Thermal escape of light atoms such as hydrogen and helium can occur from the exosphere (the uppermost layer of the atmosphere where the mean free path between collisions exceeds the scale height). Escape is efficient if the mean thermal speed is a significant fraction of the escape velocity such that a nonnegligible number of molecules in the 'tail' of the Maxwellian (thermal) distribution have speeds above the escape velocity. Extreme and vacuum ultraviolet (UV) radiation from the Sun (mostly in the 121.4 nm Lyman- α line of hydrogen) is absorbed and converted into heat in the Earth's thermosphere. The modern thermosphere lies above 400 km and has a temperature of 1200 K. Nonthermal escape mechanisms, driven by photochemical and other energetic processes, also operate. All these processes create energetic particles by photolytic, electron impact, or ionic reactions. In the absence of a magnetic field, direct momentum transfer may result in knocking atoms from the exosphere in a process known as 'sputtering.' Ions may also migrate to the polar region, where the magnetic field lines are open to the tail of the magnetosphere, and they can readily escape along these field lines. In charge exchange, H atoms lose an electron to a heavier ion, typically O⁺, and the resulting proton is accelerated by the electric field of the solar wind to exceed the escape velocity. The ionization potentials of O and H differ by only 0.02 eV. This difference is smaller than the thermal energies corresponding to typical upper atmosphere temperatures, and as a consequence the charge transfer process is very efficient.

Hydrogen loss from the exosphere is very efficient, but the actual rate (3.0×10^8 atoms cm⁻² s⁻¹) of escape from the modern oxygen-containing atmosphere is limited by the transport of hydrogen from deeper in the atmosphere. Huntén's limiting flux theorem relates the maximum escape flux of hydrogen to the abundance of total hydrogen in the mesosphere, determined largely by chemical sources and transport. The escape rates of hydrogen in the past were probably much higher than the present rate. The primary reason is that the early atmosphere probably lacked oxygen: on the modern Earth, hydrogen is 'trapped' by recombination with oxygen to form water in the lower atmosphere before it can reach the upper atmosphere and escape. A second reason is that the Sun was more active in the past, providing a higher flux of UV radiation to power hydrogen escape. The flow of hydrogen may even have been sufficiently massive to cause the hydrodynamic escape of heavier gases by momentum transfer.

Biology contributes to atmospheric evolution by modulating the interconversion of compounds and the exchange of

Table 2 The reservoirs of the major volatiles on the Earth (mantle quantities are uncertain)

	Reservoir	Size (MPa)	Climate role
H ₂ O	Atmosphere	<0.001	Greenhouse gas, carbonate sink, weathering, biology, plate tectonics
	Ocean	26	
	Hydrated crust	10	
	Mantle	~100	
	Total	136	
CO ₂	Atmosphere	0.000 03	Greenhouse gas
	Ocean	0.0002	
	Hydrated crust	4	
	Mantle	~26	
	Total	30	
N ₂	Atmosphere	0.078	Buffer gas, enhances effect of greenhouse gases
	Crustal rocks	0.025	
	Mantle	~0.1	
	Total	0.2	

compounds between the atmosphere and other reservoirs. The paramount example of this is oxygenic photosynthesis, which in effect partitions CO_2 into organic carbon and oxygen:

If the organic carbon is prevented from being immediately reoxidized (e.g., by combustion or by aerobic respiration in other organisms), the oxygen can enter the atmosphere. At some point in the past, photosynthetic production was able to overwhelm the sinks of oxygen, and the atmospheric mixing ratio of O_2 increased dramatically – an event that would never have occurred without the intervention of biology.

Biology is also responsible for repartitioning carbon dioxide between the atmosphere, oceans, and limestone rocks (kinetically favoring the last) by accelerating the process of silicate weathering and carbonate precipitation:

Without marine organisms, carbon dioxide levels would be much higher than current values: it has been suggested that the successive development of more sophisticated marine and terrestrial organisms (e.g., plants with vascular roots) has led to a secular decrease in atmospheric CO_2 over time.

A third process where life has played an important role is the recycling of oxides of nitrogen (specifically nitrates) back into the atmosphere by denitrification, e.g.:

In the absence of biology, the formation of nitrates by UV and lightning, and their rainout from the atmosphere, would have been unchecked, removing most of the N_2 (and thus most of the atmosphere) in about 1 Gy.

Aerosols are a minor component of the terrestrial atmosphere whose importance to climate is only now being more fully understood. Aerosols are micrometer-sized particles of sulfur, organic compounds, and salts that remain suspended in the atmosphere for years. They scatter sunlight, effectively cooling the surface, and serve as cloud condensation nuclei, i.e., sites of cloud water droplet formation. Clouds can either cool (by reflecting sunlight back to space) or warm (by blocking the escape of infrared radiation). The aerosol content of the atmosphere may have evolved because of changes in ocean salinity, the surface area of the continents, and biological production of sulfur compounds and organic compounds. The Archean Earth (3.8–2.5 Ga) was probably enshrouded by a photochemical haze composed of fractal aggregate hydrocarbon aerosols. These particles would be optically thick in the UV wavelengths while the remaining, relatively transparent in the midvisible wavelengths, thus providing a UV shield without causing cooling via the antigreenhouse effect.

The Record of Atmospheric Evolution

Because most of the atmosphere is recycled on a geologically short timescale, it has no 'memory' of anything but the most recent events in the history of the Earth. The exceptions to this rule are the noble gases Ne, Ar, Kr, and Xe, which are chemically inert and too heavy to escape easily from the Earth. The rare

gases in the terrestrial atmosphere are depleted with respect to other elements when compared with their expected values in the primordial nebula that formed the planets. They also exhibit strong elemental and isotopic fractionation: heavier elements and isotopes are more abundant (Figure 1). The most plausible explanation is that these gases were components of a primordial atmosphere that escaped to space early in the history of the Earth, perhaps via a 'hydrogen wind' that was driven by intense UV radiation from the young Sun or by the giant Moon-forming impact. (Terrestrial ^{40}Ar , in contrast to its sister isotopes ^{36}Ar and ^{38}Ar , is primarily a product of the radioactive decay of ^{40}K and therefore an exception.) Models of this escape also predict the loss of essentially all N- and C-containing compounds from such an atmosphere and imply that modern N and C have a separate, later origin – either from a long-term reservoir in the Earth's interior or a late 'veneer' of extraterrestrial material.

Our knowledge of the evolution of the other reactive gases is obtained by examination of the chemical and physical effects the paleoatmosphere has had on materials preserved in the rock record. The best record – and the one that has received the most attention – is that of atmospheric oxygen. Much of this work is based on the disparate aqueous solubility of compounds of certain elements, particularly Fe, Mn, and U, in the presence or absence of atmospheric oxygen. Under anoxic conditions, iron is in its highly soluble ferrous state, but insoluble ferric oxides and hydroxides form in the presence of

Figure 1 Evidence for loss of an early terrestrial atmosphere: isotopic composition of xenon in meteorites and in planetary atmospheres, plotted relative to terrestrial atmospheric xenon. Units are parts per thousand deviation from the terrestrial composition. The atmospheres of Earth and Mars are depleted in the light isotopes relative to meteorites, which are thought to reflect the composition of the primordial nebula. The lighter isotopes may have been carried away during the early escape of a hydrogen atmosphere. After Pepin, R.O., 1989. Atmospheric composition: key similarities and differences. In: Atreya, S.K., Pollack, J.B., Matthews, M.S. (Eds.), *Origin and Evolution of Planetary and Satellite Atmospheres*. University of Arizona Press, Tucson, AZ.

even small amounts of oxygen. Sedimentary units formed in the Archean (3.8–2.5 Ga) and early Proterozoic (2.5–0.54 Ga) are characterized by banded iron formations, finely laminated deposits of iron oxides and carbonates. The distribution of these deposits suggests that iron was relatively mobile and hence oxygen was absent in the deep ocean during these epochs. Whether the presence of oxygen in shallower water is not clear: iron is conspicuously rare in carbonate formations such as stromatolites from this time. Conversely, iron concentration in Archean paleosols (ancient soils) is low, indicating that Fe remained mobile (and hence removable) during the weathering process. If these soils were in chemical equilibrium with the atmosphere, then the stability of the ferrous state constrained pO_2 levels to 10^{-4} of the present atmospheric level. Oxidized soils and deposits (red beds) in which the (ferric) iron is retained do not appear in the geological record until after 2.4 Ga.

Reduced forms of mineral sulfur (pyrite) and uranium (uraninite) are insoluble and hence resistant to removal by aqueous process. These minerals are seen in Archean deposits, but not in later Proterozoic ones, again indicating an increase in atmospheric pO_2 . The ratio of thorium to uranium in mantle-derived rocks shows a marked increase from samples older than 2 Ga to younger samples, which can be explained if recycling of U into the mantle has become less efficient owing to increased retention of (soluble) U in an oxidizing hydrosphere. Manganese is oxidized only in the presence of abundant molecular oxygen, and on the modern Earth this occurs only through the intervention of Mn-oxidizing bacteria. Mn deposits appear only during certain intervals in the geological record. The early Proterozoic was a unique period of Mn deposit formation (some of the deposits are of great economic importance). If these deposits were formed as oxides (rather than carbonates), they would be unambiguous indicators of the appearance of high oxygen levels.

Although sulfur species are not a significant component of the present-day atmosphere, and the bulk of surface S is in the ocean, sulfur deposits may serve as indicators of past oxygen levels because the rate of oxidative weathering of sulfur minerals and the transfer of S as sulfate to the oceans are controlled by atmospheric O_2 . The other input of sulfur to the ocean-atmosphere system is SO_2 in volcanic gases. Variations in atmospheric oxygen will change the relative importance of these two sources. Possible evidence for such a change is the disappearance of iron formations after 1.8 Ga. Rather than being the result of an oxidation event, the immobility of Fe could be the indirect result of a rise in atmospheric oxygen and the initiation of a 'modern' sulfur cycle, in which oxidative weathering of sulfur-bearing minerals on the continents leads to transport of sulfate to the oceans. Sulfate reduction (by bacteria) would produce elevated concentrations of sulfide in deepwater and precipitation of Fe as pyrite. Sulfur from ancient marine sediments and evaporite deposits also records a shift in the distribution of relative abundance of the two major isotopes ^{32}S and ^{34}S , suggesting an increase in sulfate reduction by bacteria. Archean rocks also provide evidence for mass-independent fractionation among a three-sulfur isotope system that includes ^{33}S (Figure 2). This fractionation pattern is unlike those produced by the oxidation of sulfur by weathering or the reduction of sulfate by biology, where

Figure 2 Evidence for a change in the sulfur cycle 2.5 Ga: the quantity $\Delta^{33}S$ is the deviation of $\delta^{33}S$ (the fractionation of the isotopes ^{33}S and ^{32}S with respect to a standard sample) away from a mass-dependent fractionation curve which relates $\delta^{33}S$ to $\delta^{34}S$ by a line with slope ~ 0.51 . All known biological and geochemical fractionation processes are mass dependent, and any samples experiencing only these effects would have $\Delta^{33}S = 0$. While all samples younger than 2 Gy have $\Delta^{33}S = 0$, older samples exhibit mass-independent fractionation which is suggestive of an important role for gas-phase (atmospheric) reactions. This fractionation may be a consequence of an anoxic Archean atmosphere and a lack of oxidative weathering of sulfide minerals. From Farquhar, J., Baoh, H., Thiemens, M., 2000. Atmospheric influence of Earth's earliest sulfur cycle. *Science* 289, 756–758.

fractionation is proportional to the mass differences between the isotopes. Mass-independent fractionation could indicate that in the absence of atmospheric oxygen during the Archean, certain gas-phase reactions were significant contributors to the sulfur cycle.

Carbon dioxide is a minor component (preindustrial $pCO_2 = 280$ ppm) of the modern atmosphere, but it is the principal incondensable greenhouse gas. Since the amounts of CO_2 in the oceans and carbonate rocks are equivalent to 0.023 and 40 atm, respectively, there is the potential for substantial evolution in atmospheric carbon dioxide levels. A higher concentration of atmospheric CO_2 is suspected as one cause for a warmer climate during the Jurassic and Cretaceous periods. It has been suggested that there was a secular decrease in atmospheric CO_2 over time, with levels as high as 300 hpa during the early Archean. The rationale for this hypothesis is the observation that the temperature-sensitive weathering of silicate rocks, which produces calcium and magnesium cations and alkalinity, could have regulated the formation of carbonate rocks and sequestration of CO_2 from the atmosphere. The weathering process acts as a global thermostat: lower carbon dioxide levels would bring about lower temperatures, which would slow weathering and carbonate formation, allowing CO_2 levels to rise. Likewise, lower solar luminosity in the past would have been compensated by higher pCO_2 . Although the geochemical logic is compelling, there is actually little evidence to confirm or refute the hypothesis. Under low oxygen conditions, high CO_2 concentrations would have favored the precipitation of minerals such as siderite (iron carbonate). Absence of siderite in some paleosols may place a constraint on atmospheric CO_2 .

The history of nitrogen, the primary but relatively inert component of the modern atmosphere, is even more poorly constrained by the geological record. The relative abundance of the isotopes ^{15}N and ^{14}N in kerogens (organic molecules that are the sedimentary product of the breakdown of living organisms) in Precambrian rocks indicates a shift in relative abundance from lighter to heavier nitrogen during the late Archean. One explanation for the shift is an increase in atmospheric oxygen content that led to an increased production in nitrate, either by atmospheric processes or by biology. Nitrate compounds are used by microorganisms, which either convert them to a reduced form (ammonia) to include in cellular material eventually, or use them as an oxidant in energy generation (denitrification). Reduction of nitrates by denitrifying bacteria yields isotopically light N_2 gas and isotopically heavy residual nitrates. As a result, surface nitrogen, including that in cells, becomes relatively heavy with respect to the atmosphere. The shift is small (about 10 ppm) and it is unlikely that there was a large change in the partitioning between the atmospheric reservoir (the largest) and surface nitrogen between the Archean and Proterozoic. Thus the nitrogen isotopes may be telling us more about the history of atmospheric oxygen than that of nitrogen.

Atmospheric Evolution and the Gaia Hypothesis

According to accepted theories of the evolution of main sequence stars, of which the Sun is a typical member, solar luminosity has steadily increased by about 40% since the Sun formed. The mean surface temperature of a planet like the Earth is determined by energy balance. If the composition of the atmosphere had remained unchanged, the Earth's mean surface temperature would have been below the freezing point of water before about 2 Ga. But the sedimentary record shows that liquid water has always been present on Earth. A plausible resolution of the 'faint young Sun' paradox is that the early atmosphere contained more greenhouse gases (e.g., CO_2). Two greenhouse gases other than CO_2 that have also been considered for this role are ammonia and methane. Both gases have strong absorption bands that fall within the spectral wavelength range or 'window,' where the Earth reradiates most of the solar energy it receives back to space, but outside the primary CO_2 absorption band at 15 mm. Their abundances (mixing ratios) in the atmosphere will depend on their rates of production and destruction. The largest present-day sources of methane and ammonia are biological, and that is likely to have been the case at early times as well. While ammonia is a very effective absorber of infrared radiation, it is easily destroyed by UV radiation and is unlikely to have been abundant enough in the Archean atmosphere. Methane, on the other hand, has a chemical lifetime of 10 years: CH_4 is stable with respect to molecular oxygen, but reaction with hydroxyl radicals (OH) from the photolysis of water vapor produces CH_3 , which does readily react with O_2 . In the absence of oxygen to remove the hydrogen also produced by photolysis, OH can recombine with H and is no longer an effective sink for methane. The modern production rate can maintain a CH_4 mixing ratio of 10^{-3} in an anoxic atmosphere, a level that can act in concert with a modest amount of

atmospheric CO_2 to maintain Archean temperatures above freezing. However, the dominant modern source of methane is the microbiota in the anoxic guts of termites and ruminants. It is not clear what the production rates would have been in the Precambrian before animals existed.

It has been suggested that the existence and evolution of life on this planet may have had a profound impact on the climate by regulating the amounts of CO_2 and other greenhouse molecules in the atmosphere, or by controlling the production of aerosols and thereby modulating cloud formation. Observations of the fundamental role of biology in the cycling of atmospheric gases is one basis for the 'Gaia' hypothesis in which the biosphere is conceived as regulating climate to maintain suitable conditions for biological activity. The ability of the biosphere to maintain a global environment that is optimal for life is known as homeorhesis. That the terrestrial atmosphere has been subject to homeorhesis by the biosphere throughout its long history is an intriguing hypothesis but difficult to prove. Investigations into the evolution of Earth's atmosphere not only grapple with profound questions about our planet's habitability but also address the possible existence and detection of habitable planets and life around other stars. Counter examples of the Gaia hypothesis include the Great Oxygenation Event (GOE) and Snowball Earth. The GOE around 2.4 Ga might have been triggered by cyanobacteria, which appeared 200 My before. The appearance of oxygen resulted in the loss of the methane greenhouse. In the subsequent Snowball Earth, peroxides could have accumulated in the ice, providing a potent source of oxidants that were lethal to the anaerobic biosphere.

Synopsis

The Martian atmosphere is mainly CO₂ with a mean surface pressure of 6.1 mb. Its thermal structure, wind systems, and photochemistry are similar to Earth's but with important differences. The present climate is characterized in terms of the seasonal cycles of dust, water, and CO₂. Past climates were different due to large changes in Mars' orbital characteristics, and a thicker atmosphere that existed very early in its history. Liquid water flowed on the surface at these early times, but is not stable on Mars today.

Introduction

The atmosphere of Mars is similar to Earth's; it is thin and relatively transparent to sunlight. Mars' spin rate and axial tilt are also Earthlike. Thus, it falls into the category of a rapidly rotating, differentially heated atmosphere with a solid lower boundary. However, there are important differences. The Martian atmosphere is primarily carbon dioxide with a much lower surface pressure, and Mars does not have oceans and an Earthlike hydrological cycle so latent heat release is not as important as it is for Earth. It does, however, contain suspended dust particles, which do provide significant diabatic heating.

Mars also appears to have experienced significant climate change. Today, Mars is cold and dry. Yet spacecraft images provide compelling evidence that the planet's climate was different in the past. Layered terrains in the polar regions may have been created by climate change associated with astronomical variations in Mars' orbit parameters. Valley networks and degraded craters in ancient terrains may be the result of a thicker atmosphere early in Mars' history. And there is some evidence that the planet may have had an ocean at some time in its past, perhaps on several occasions.

Composition and Mass

The composition of the Martian atmosphere was determined in the mid-1970s by the Viking Landers. The results of their measurements are given in Table 1. Carbon dioxide is the principal constituent, followed by nitrogen, argon, oxygen, and carbon monoxide. Trace amounts of the noble gases are also present. Additional minor and highly variable constituents include water vapor, ozone, and dust particles. Together, these gases exert a mean annual surface pressure of 6.1 mb, which corresponds to an average column mass loading of 164 kg m⁻². More recent measurements by the Mars Science Laboratory confirm the Viking measurements, but find equal abundances for N₂ and ⁴⁰Ar (both 1.9%). The change may be the result of different measurement techniques and/or an indication of time variable phenomena.

Temperatures

Temperatures depend critically on Mars' orbit parameters. These are listed in Table 2. The main points are that (1) Mars

receives about half as much annually averaged sunlight as Earth, (2) its orbit is much more eccentric than Earth's, and (3) its rotation rate and obliquity are similar to Earth's. Consequently, Mars is colder, experiences a much greater seasonal change in available insolation (40% compared to 6% for Earth), has Earthlike diurnal and seasonal changes, and has a similar Coriolis parameter.

Except during very dusty periods, the atmosphere of Mars is semitransparent to solar radiation. Consequently, its temperature structure is influenced by thermal emission from the surface. Models indicate that the globally averaged surface temperature on Mars is ~200 K. However, because Mars lacks oceans, its surface temperatures undergo considerable seasonal, diurnal, and latitudinal variation. The lowest surface temperatures (~150 K) occur in the polar regions during winter and are associated with the condensation of CO₂ on the surface. The highest surface temperatures (~300 K) occur in the southern subtropics, when Mars is closest to the Sun. In these same regions, diurnal variations can exceed 100 K.

Approximately 10–20% of the radiation emitted by the surface is absorbed in the atmosphere. Some of the absorbed radiation is reradiated back to the surface, producing a modest greenhouse effect. A convenient measure of the greenhouse effect is the difference between the average surface emission temperature T_{se} (~215 K) and the planet's effective temperature T_{eff} (~210 K). For Mars, this difference is about 5 K. By comparison, the Earth's atmosphere produces a much stronger greenhouse effect (~33 K) due to a much greater abundance of water vapor and other greenhouse gases.

Table 1 Composition of the Martian lower atmosphere (<120 km); the global mean annual surface pressure is ~6.1 hPa

Constituent	Abundance
CO ₂	95.32%
N ₂	2.7%
⁴⁰ Ar	1.6%
O ₂	0.13%
CO	0.07%
H ₂ O	0.03% (variable)
Ne	2.5 ppm
Kr	0.3 ppm
Xe	0.08 ppm
O ₃	0.04–0.2 ppm (variable)
Dust	0 to >> 5 (visible optical depth)

Table 2 Orbital parameters for Mars and Earth

Property	Mars	Earth
Mass, kg	6.46×10^{23}	5.98×10^{24}
Radius, m	3394	6369
Gravity at surface, m s^{-2}	3.72	9.81
Orbit eccentricity	0.093	0.017
Semimajor axis, AU	1.52	1.0
Solar flux, W m^{-2}	590	1360
Length of year, Earth days	687	365
Length of solar day, s	88 775	86 400
Spin-axis inclination, °	25.2	23.5
Longitude of perihelion, °	250	285

Dust particles in the atmosphere strongly influence the transmission of solar and infrared radiation. Based on lander and orbiter measurements, their mean particle radius is $\sim 1.5 \mu\text{m}$. Particles in this size range interact efficiently with sunlight and less so with thermal radiation. During the Viking mission, the daily mean temperature at the Viking Lander 1 site declined by several degrees Kelvin during the passage of a dust storm. This suggests that dust particles produce a modest antigreenhouse effect (i.e., they reflect more sunlight back to space than they emit in the infrared range to the surface).

Vertical Structure

Temperatures decrease with height in the Martian atmosphere, as they do on Earth. As illustrated in Figure 1, the variation of temperature with height on Mars gives rise to a troposphere,

Figure 1 Vertical structure of the Martian atmosphere. Colored curves are temperatures inferred from deceleration measurements aboard the Viking 1 (blue), Viking 2 (green), and Pathfinder (red) Landers.

a mesosphere, and a thermosphere. Mars does not have a stratosphere because it lacks a significant ozone layer.

The troposphere on Mars is deep by comparison to Earth. Based on Viking and Pathfinder Lander entry measurements, the troposphere on Mars extends to almost 60 km with an average lapse rate of $\sim 2.5 \text{ K km}^{-1}$. On Earth, the troposphere is about 12 km deep, and the lapse rate is $\sim 6.5 \text{ K km}^{-1}$.

On both planets, the observed lapse rates are much less than the dry adiabatic lapse rate (Table 3). For Earth, this is due to latent heat release associated with the condensation of water vapor. For Mars, the additional heating comes from the absorption of solar radiation by suspended dust particles. On both planets, temperatures are further stabilized by vertical heat fluxes associated with large-scale circulation systems.

Theoretical studies indicate that daytime boundary layer convection could extend to very high altitudes ($\sim 10 \text{ km}$) on Mars. In such regions, the lapse rates should be close to the adiabatic value. Evidence for deep daytime convection on Mars was found in the Viking Lander 1 entry profile (Figure 1), which indicated a near-adiabatic lapse rate between the surface and 6 km. Above 15 km, temperatures continue to decrease with height, but are controlled almost entirely by radiation rather than convection.

In the Martian mesosphere, temperatures become nearly isothermal. Superimposed on this structure are oscillations due to the adiabatic heating and cooling associated with vertically propagating planetary waves. These waves are associated with a global system of thermal tides. As the tides propagate upward, their amplitude increases. Eventually, they produce superadiabatic lapse rates, at which point the waves 'break' and generate local mixing. There are several locations in the Viking entry profiles where wave breaking is indicated.

In the thermosphere, temperatures increase because of heating due to the absorption of radiation in the far and extreme ultraviolet ranges. This also occurs on Earth. The base of the thermosphere is about 80 km on Earth and about 100 km on Mars.

Photochemistry

Photochemical reactions occur throughout the Mars atmosphere. Carbon dioxide, the main constituent, is readily dissociated by ultraviolet radiation:

Table 3 General circulation parameters for Mars and Earth

Property	Mars	Earth
Scale height, km	10.2	7.6
Mean temperature of lowest scale height, K	200	260
Dry adiabatic lapse rate, K km^{-1}	4.3	9.8
Mean lapse rate of lowest scale height, K km^{-1}	2.5	6.5
Brunt Väisälä frequency, 10^{-2} s^{-1}	~ 0.06	1.12
Radiative damping time, days	~ 2	> 20
Winter westerly jet speed, m s^{-1}	80	30
Planetary Rossby number	0.05	2.0
Rossby deformation radius, km	920	1150

However, the reverse reaction

(where M is any nonreactive molecule) is very slow such that the oxygen atoms tend to form O_2 and O_3 rather than CO_2 . The time required to convert the present CO_2 atmosphere into one composed predominantly of CO and O_2 is only several thousand years. Yet CO_2 is the dominant constituent, while CO and O_2 are scarce. How CO_2 is stabilized in the Martian atmosphere is a major focus of Martian photochemical studies.

The prevailing view is that CO is oxidized by OH via

The OH itself is ultimately derived from the photolysis of water vapor. Thus, even though water vapor is a minor constituent, it may play a very important role in maintaining CO_2 as the dominant constituent. Support for the importance of this water chemistry comes from the detection of molecular hydrogen (H_2) in the atmosphere and the distribution and abundance of ozone.

Ozone abundances on Mars are much less than on Earth, and they range from below the threshold of detection in warm tropical regions to as high as 150×10^{15} molecules cm^{-2} in the cold polar regions. Ozone is produced when O and O_2 combine, and is destroyed by ultraviolet dissociation. However, in the absence of additional atmospheric sinks, ozone would be much more abundant than observed. The H and OH produced by water photolysis provide this additional sink by using the same catalytic cycle that operates in Earth's stratosphere, namely

Since the source of odd hydrogen is water vapor, ozone will be depleted in regions where it is abundant, and plentiful in region where it is absent. This anticorrelation between ozone and water vapor has been observed and provides support for the importance of water as a key chemical ingredient of the Martian atmosphere.

During the early 2000s, methane (CH_4) was detected in the Martian atmosphere at the 10 ppb level. The detection is significant since none is expected and its presence at these levels could be the result of a biological source. However, the reported seasonal and latitudinal variability has been difficult to explain since methane is expected to have a long lifetime (200–300 years). This variability implies there are strong sources and sinks for methane, which have yet to be identified and confirmed. Furthermore, the Mars Science Laboratory did not detect any significant methane in the Martian atmosphere during its first year of operations. Thus, the validity of the earlier measurements is controversial.

Escape Processes

Escape occurs in the exosphere, which begins on Mars at about 230 km. In the exosphere, the probability of collisions is so small that particles execute ballistic trajectories, some of which carry them away from the planet. The most important gases that can escape from Mars are hydrogen, oxygen, and nitrogen.

Molecular hydrogen (H_2) is one of the products of water vapor photolysis. Below the homopause, H_2 is well mixed and

has a long lifetime (10^3 years). Above the homopause, it is converted into atomic hydrogen and has enough thermal kinetic energy to escape to space. Ultraviolet spectrometers aboard the Mariner 9 spacecraft have detected atomic hydrogen escaping from Mars.

The escape of hydrogen implies that there must be a sink for O_2 . Otherwise, the amount of O_2 would double in about 2×10^5 years. Loss of oxygen can occur through the oxidation of surface materials and/or escape to space. Loss to the surface requires the continual exposure of surface materials and is not likely to be significant on 10^5 -year time scales. On the other hand, atomic oxygen is too heavy to escape on the basis of its thermal motion alone. However, it can escape when ionized oxygen molecules (O_2^+) in the ionosphere recombine with electrons. The recombination dissociates the molecule into its constituent atoms with enough kinetic energy to escape. This nonthermal escape mechanism – known as ‘dissociative recombination’ – yields an oxygen escape flux that is theoretically expected to adjust itself until it balances the hydrogen loss (i.e., for every oxygen atom that escapes, two hydrogen atoms also escape). In effect, water would be leaving the planet. However, observations suggest that the oxygen escape flux is much less than this prediction, indicating that the atmosphere is not in redox balance at the present time.

General Circulation

Although the meteorological database for Mars lacks the temporal and spatial coverage needed to fully characterize its general circulation, much can be inferred from it – particularly, in connection with general circulation models. Figure 2 is a schematic illustration of our present understanding of the general circulation. From the data and models, the main components of the general circulation are a zonally symmetric mean meridional circulation, stationary and propagating planetary waves, thermal tides, and a mass flow associated with the seasonal cycling of CO_2 into and out of the polar regions. The latter is a unique feature of Martian meteorology.

The mean meridional circulation dominates the lower latitudes and is characterized by a deep Hadley circulation, which undergoes significant seasonal variation in structure and intensity. At the equinoxes, two roughly symmetric Hadley cells develop that share a common rising branch centered at or near the equator. At the solstices, the two Hadley cells give way to a single cross-equatorial circulation. Models indicate that the intensity of the Hadley cell mass flux varies from 10^9 kg s^{-1} at the equinoxes to 10^{10} kg s^{-1} at the solstices.

To some extent, the Hadley cell is a mathematical construct in that the circulation is not in itself zonally uniform. In the rising branch, for instance, much of the upward motion may take place in narrow convective plumes embedded in a broader pattern of overall sinking motion. When averaged over longitude, the net result is upward flow. Thunderstorms play such a role in the Earth's tropics. While there are good theoretical reasons to expect that a similar situation exists on Mars, better observations are needed to confirm this.

The zonal wind component of the mean meridional circulation has been inferred from temperature data through the gradient wind relationship. An illustration of winds derived in

Figure 2 Schematic illustration of the general circulation on Mars.

this manner is shown in [Figure 3](#). Application of the gradient wind relationship to Mars indicates that easterly winds prevail in the tropics at all seasons, and in the summer hemisphere at the solstices. Westerlies prevail in the winter hemisphere at the solstices, and at middle and high latitudes during the equinoxes. If zonal winds at the surface are relatively weak, as was indicated by the Viking, Pathfinder, and Phoenix Landers, then

the thermal data indicate that the westerly jet stream in the winter hemisphere is typically on the order of 100 m s^{-1} .

At high northern latitudes during winter, the Viking Landers detected eastward propagating disturbances of high- and low-pressure systems. These traveling disturbances are very similar to terrestrial ‘weather’ systems in that southerly (northerly) winds are generally associated with falling (rising) pressures

Figure 3 Time-averaged zonal mean winds as a function of latitude and pressure (altitude) for winter in the southern hemisphere. Winds are derived from thermal emission spectrometer (TES) data using the gradient wind relationship. Red-colored contours are isotherms (K); blue-colored contours are wind speed (m s^{-1}).

and warm (cold) air advection. Theory suggests that the transient eddies arise from baroclinic instability. Both theory and observations indicate that the dominant zonal wave number of the transient eddies varies between 1 and 4, and that they propagate around latitude circles with phase speeds between 10 and 20 m s⁻¹.

Dust Storms

The surface of Mars is mantled with a fine dusty material that is lifted into the atmosphere when surface winds become strong enough to initiate particle motion. Because of the low density of the Martian atmosphere, dust-raising winds must be quite strong. Viking Lander 1 measured surface winds gusting to 30 m s⁻¹ during the passage of a dust storm, suggesting that this is the minimum wind speed required to initiate lifting. However, the dust-raising process is complicated and the threshold for lifting can vary depending on surface properties and atmospheric stability.

Numerous dust storms occur each Martian year and are generally classified according to size. From the smallest to largest, they are dust devils (<10⁻¹ km²), local storms (~10³ km²), regional storms (~10⁶ km²), and planet-encircling storms (>10⁶ km²). In general, the smaller storms have shorter lifetimes and occur much more frequently than the larger storms. Dust devils, for example, occur daily and last from minutes to hours, whereas planet-encircling storms occur quasiannually and can last for months.

Dust devils are typically tens of meters in diameter and several kilometers tall. Some have been observed to heights of ~8 km. They generally form over smooth terrain within several hours of local noon. From orbit, these systems have been detected from the shadows they produce and from the trails they leave on the surface. From the surface, they have been detected in meteorological data and camera images. Dust devils are believed to be significant contributors to Martian atmospheric dust loading.

Local dust storms are also quite common. Based on Mars Global Surveyor (MGS) images, as many as 2000 local storms occur each Martian year. This gives a daily-averaged rate of 2–3 storms per Martian day. They have typical lifetimes of less than several days. Local dust storms tend to form along the edge of the polar caps and at the midlatitudes of both hemispheres. These systems often have a distinct convective morphology and can be quite optically thick.

Regional storms have been observed at nearly all seasons, but are most frequent during southern spring and summer. Most regional storms develop within ±30° of latitude, although there is a distinct bias toward the southern hemisphere. Regional storms can last from days to weeks. These storms can drift a significant distance from their original location, and new satellite storms can develop that are quite remote from the original center.

Planet-encircling storms are the least frequent but the most spectacular of Martian dust storms (Figure 4). They spread dust around all longitudes and most latitudes to heights in excess of 50 km. They generally begin in the southern hemisphere during southern spring and summer. None have been observed at other seasons. They start as regional storms and then expand in longitude, then in latitude. To date, eight planet-encircling storms have been confirmed. The most recent occurred in late April 2009 and was observed by the Mars Reconnaissance Orbiter (MRO).

The mechanisms responsible for the Martian dust storms are poorly understood. Dust devils are probably related to strong daytime convective heating, as they are on Earth. For the larger storms, however, radiative feedback effects must be important. Suspended Martian dust particles interact efficiently with sunlight. Thus, as dust loading increases, so does the direct in situ heating of the atmosphere. This then intensifies the circulation, which lifts additional dust. This positive feedback continues until the supply of mobile dust particles on the surface is exhausted, or the dust loading becomes so high that the atmosphere stabilizes and further lifting is suppressed.

Figure 4 Hubble Space Telescope images of Mars before (left) and during (right) the 2001 global dust storm.

Clouds

Water vapor in the Martian atmosphere is controlled by saturation. Thus, water-ice clouds are fairly common. However, their water content is generally low (several $\text{pr-}\mu\text{m}$). Clouds are most prominent during northern summer in the tropics and during winter in the polar regions. The northern-summer tropical clouds are commonly referred to as the aphelion cloud belt (ACB) since Mars is near its aphelion at this season. These clouds form at altitudes above 15 km and are generally diffuse, although optically thick clouds can often be seen over the volcanoes in the Tharsis province (Figure 5). The winter polar clouds form in the lowest scale height and are called ‘polar hoods.’ These clouds are widespread, are optically thick, and often contain wave clouds forced by topographic obstacles such as craters. The north polar hood is more prominent than the south polar hood. In general, water ice clouds are more common in the northern hemisphere than in the southern hemisphere.

The size and shape of Martian water ice clouds are not well constrained. Retrievals from remote-sensing data indicate that their effective radii are typically in the 1–4 μm range, although light detection and ranging measurements at the Phoenix Lander site suggest sizes as large as 35 μm in clouds near the surface. Submicron-sized particles have also been inferred for thin hazes at high altitudes. These retrievals further suggest that there is very little dispersion in particle sizes and that their shapes are multifaceted and equidimensional.

While latent heat release is not important for Martian clouds, recent studies indicate that the radiative effect of clouds can significantly alter the thermal structure of the atmosphere. Clouds in the ACB warm the atmosphere by absorbing infrared

radiation upwelling from the warmer surface, while clouds in the polar hoods cool the atmosphere by emission to space. Thus, cloud radiative effects tighten the equator-to-pole temperature gradient and increase the baroclinicity of the atmosphere.

Clouds of CO_2 ice also form in the Martian atmosphere. In the winter polar regions, atmospheric temperatures can reach the frost point of CO_2 (<150 K). The presence of CO_2 ice clouds in this region has been inferred from thermal emission and laser altimeter data. CO_2 ice clouds also form at very high altitudes (>50 km) in tropical regions. Like water ice clouds, the physical properties of CO_2 ice clouds are uncertain, but retrievals from remote-sensing data and theoretical microphysical studies suggest they are larger than water ice particles with effective radii up to 60 μm . Unlike water ice clouds, however, latent heat release is important for CO_2 ice clouds and may result in buoyant convection.

Climate

The climate of Mars is characterized in terms of the seasonal cycles of CO_2 , water, and dust. Each of these cycles involves the exchange of material between surface and atmospheric reservoirs. The exchange itself is driven by daily and seasonal variations in insolation. The atmosphere plays a major role in these cycles by serving as the agent of transport from source to sink.

The condensation of CO_2 during winter and its subsequent sublimation during spring give rise to the familiar waxing and waning of the polar caps. Approximately 25% of the Martian atmosphere is cycled into and out of the polar regions each year by this process. The signature of this cycling can be seen in the measurements of surface pressure by the Viking Landers (Figure 6). Recent measurements by the Mars Science Laboratory show similar trends in surface pressure.

MOC observations of the 2001 planet-encircling dust storm. *Icarus* 186, 60–96. <http://dx.doi.org/10.1016/j.icarus.2006.08.019>. Credit: NASA, JPL, and MSSS.

Figure 6 Seasonal variation of the daily-averaged surface pressure on Mars as measured by the Viking Landers. Season is expressed in terms of L_s , an angular measure of the planet's orbital position. $L_s = 0^\circ$ corresponds to the northern spring equinox, $L_s = 90^\circ$ is the summer solstice, $L_s = 180^\circ$ is the fall equinox, and $L_s = 270^\circ$ is the winter solstice.

At each site, there is a pronounced semiannual variation. The variation is semiannual rather than annual because while one cap is growing, the other cap is retreating. However, the variation is asymmetric, with a much deeper minimum occurring during southern winter than during northern winter. This asymmetry is a direct consequence of Mars' orbital eccentricity. Southern winters are much longer than northern winters such that much more CO₂ condenses out of the atmosphere. As a result, pressures are the lowest during the middle of southern winter and highest in late spring when the cap disappears.

At both poles, however, the caps never completely disappear during summer. At the North Pole, CO₂ frost completely sublimates by summer and leaves behind an underlying water ice cap. Near the South Pole, surface CO₂ frost appears to survive all summer long. Thus, the summer caps have different compositions: CO₂ frost in the south, and water ice in the north. The reason for this compositional asymmetry is not understood. Furthermore, the year-to-year changes in the morphology of the residual south cap suggest that it may be slowly eroding and possibly disappear completely within several Mars decades since it appears to be relatively thin (~5 m thick). Thermal data show that a thin layer of water ice underlies the visible CO₂ cap. Recent radar measurements indicate that as much as 5 mb global equivalent of CO₂ ice may be buried to depths of 500 m or more below that thin layer of water ice.

When water ice is exposed at the North Pole during summer, it sublimates into the atmosphere. Winds transport this water all around the planet. The Viking, MGS, and MRO orbiters have mapped the resulting seasonal and spatial variation of atmospheric water vapor. An example is shown in Figure 7. Maximum abundances of about 60 pr- μ m are found at high northern latitudes during summer. The northern-summer ice

cap is therefore an important source of atmospheric water vapor. Minimum observed abundances of less than several pr- μ m occurred in the polar regions during winter. Because of their low temperatures (~150 K), the seasonal CO₂ caps will act as a sink for any atmospheric water vapor that is brought in contact with them. For the current epoch, this implies that on an annual averaged basis, there is a net transfer of water from the north cap to the south cap. The Mars Express orbiter has observed water frost mixed with CO₂ frost at both poles, thus supporting this conjecture.

Climate Change

There is good evidence that Mars has experienced climate change in the recent geological past. Both polar regions are characterized by extensive layered terrains, which were likely formed by atmospheric sedimentation processes that were modulated in time. Furthermore, there are numerous nonpolar ice-related deposits that cannot be produced in today's climate such as tropical mountain glaciers, gullies, pedestal craters, polygons, and a latitude-dependent ice-rich mantle. The most widely accepted theory on the origin of these features is climate change forced by orbital variations. According to this theory, Mars' orbital parameters vary in a quasiperiodic fashion, and this alters the seasonal and latitudinal variation of zonally averaged insolation, which changes the general circulation and the dust, water, and CO₂ cycles.

The key orbital parameters are the obliquity and eccentricity. Because Mars does not have a large stabilizing moon, these parameters can vary significantly on time scales of tens to hundreds of thousands of years. Orbit models can accurately predict how these parameters have varied during the past 20 My (Figure 8). Beyond 20 My, however, the solutions

Figure 7 TES zonally averaged column water vapor abundances (pr- μ m) as a function of latitude and season (expressed in terms of L_s). Figure 8 Variation of the (a) obliquity (top) and (b) eccentricity (bottom) of Mars for the past 20 My. Reproduced from Laskar, J., Correia, A.C.M., Gastineau, M., Joutel, F., Levrard, B., Robutel, P., 2004. Long term evolution and chaotic diffusion of the insolation quantities of Mars. *Icarus* 170, 343–364. <http://dx.doi.org/10.1016/j.icarus.2004.04.005>.

become chaotic and are predictable only in a statistical sense. The obliquity is the most important parameter. The current value is 25.2° , but it has varied from between 15 and 45° during the past 20 My, and between nearly 0 and 80° over the full history of the planet. The most likely value of the obliquity is $\sim 41^\circ$. Thus, today's obliquity is not representative of most of Mars' history.

As obliquity increases, annually averaged insolation increases at the poles and decreases at the equator. Consequently, the polar regions warm with respect to the equator. At such times, model studies indicate that water ice at the poles would be transferred to lower latitudes, which may explain some of the features mentioned in this article. Furthermore, surface pressures, and hence the atmospheric dust loading, may increase if the CO_2 ice buried at the South Pole is driven into the atmosphere. Surface pressures could also increase if any exchangeable adsorbed CO_2 is stored within the high-latitude regolith.

At low obliquities, polar regions cool and tropical regions warm. During these times, permanent CO_2 polar caps would form that would act as a sink for both CO_2 and water. Surface pressures would fall, possibly as low as 0.3 mb. Under these circumstances, dust storms would cease, the atmosphere would clear, and seasonal variations would subside. Thus, by modulating the latitudinal distribution of solar insolation, obliquity oscillations provide a mechanism to mobilize and redistribute dust, water, and CO_2 around the planet.

Early Mars

Three lines of evidence suggest that early in its history (>3.5 Gy ago), Mars had an atmosphere much different

from what it has today. The first are geochemical in nature and are based on the mineralogy of surface materials. The second are isotopic in nature and are based on measurements of isotopes in the atmosphere and in the SNC meteorites. The third are geological in nature and are based on the morphology of the surface and its implications for fluid flow.

An example of a geochemical argument is the presence of phyllosilicates (clays) on ancient Martian terrains. Phyllosilicates are the end products of the aqueous weathering of basaltic materials and therefore imply that liquid water was abundant when they formed. The liquid water could be the result of an active hydrological cycle with rainfall and runoff, which implies a warm climate system. Alternatively, it could have been part of a subsurface hydrothermal system driven by internal heating, which has no implications for climate conditions. Geochemical arguments tend to be somewhat ambiguous in their implications for the early Mars climate system.

An example of an isotopic argument is the observed enrichment of N^{15} relative to N^{14} . Like oxygen, nitrogen can escape from Mars nonthermally by dissociative recombination. Above the homopause (~ 120 km), the heavier isotope decreases in concentration more rapidly with height than the lighter one. Consequently, at the exobase (~ 200 km), there are fewer N^{15} atoms available for escape. Over the lifetime of the planet, this leads to an enrichment of N^{15} relative to N^{14} . The observed value is $\text{N}^{15}/\text{N}^{14} = 0.006$, or approximately 1.6 times the terrestrial value. This implies a higher abundance of nitrogen in the past, which also implies a higher abundance of CO_2 . Isotopic arguments like this generally indicate that a thicker atmosphere existed in the past.

Two features in the geologic record provide compelling evidence for a different environment on early Mars. They are the valley networks and the degraded crater rims. Both are found in terrains estimated from crater counts to be 3.5–3.8 Gy old. These terrains are found mostly in the southern hemisphere. An example is shown in Figure 9. The valley networks resemble terrestrial drainage systems and appear to have formed by erosion associated with rainfall and runoff. Such erosion can also explain the degraded crater rims. These features provide the best evidence for warmer, wetter conditions with an active hydrological cycle early in Mars' history.

The most likely way to achieve warmer and wetter conditions on early Mars is through a greenhouse effect, and the most likely greenhouse gases are CO_2 and water vapor. A strong greenhouse effect is required because the sun was 25% less luminous 3.5 Gy ago. At present, neither CO_2 nor water vapor is present in sufficient quantities to produce much greenhouse warming. However, these may have been present in ample quantities in the early Mars atmosphere. Unfortunately, climate models based on pure CO_2 – H_2O atmospheres have been unable to reproduce the conditions needed for sustained rainfall and runoff. Even when supplemented with additional greenhouse gases such as SO_2 or CH_4 , thicker CO_2 atmospheres are only marginally capable of significant warming. Thus, a sustained greenhouse effect capable of supporting liquid water on the surface has not yet been convincingly demonstrated for early Mars.

Figure 9 Huygens crater on Mars (10° S, 55° E). Valley networks drain toward the north into a depression where degraded crater rims can be seen (upper right and upper left). Figure provided courtesy of Carr, M.H., 1996. *Water on Mars*, Oxford University Press, New York, 229 pp. Credit: NASA, JPL.

An alternative hypothesis is that the valley networks were formed in multiple transient events associated with impacts. Meteors larger than 10 km in diameter deliver enough energy to temporarily generate a very warm and wet climate capable of providing significant rainfall for hundreds or perhaps thousands of years after the impact. This hypothesis is attractive because Mars obviously experienced a high impact rate early in its history, and we know that impacts can significantly alter the climate system on Earth. However, the predicted erosion rates of impact-generated climate change fall short of the required amount. Thus, a convincing explanation for the mineralogical, isotopic, and geological evidence about early Mars has yet to emerge.

The Future

Our knowledge of Martian atmosphere and climate has greatly benefited from a vigorous international Mars exploration program. Beginning with the MGS mission in 1996, eight spacecraft missions have successfully reached the red planet to

study its mysteries from orbit and the surface (Table 4). On 5 August 2012, the Mars Science Laboratory landed the *Curiosity* rover in Gale Crater with plans to operate it for at least one Mars year. The Rover Environmental Monitoring Station on *Curiosity* gathers hourly meteorological data to extend our record of the surface environment. In late 2013, NASA will launch the Mars Atmosphere and Volatile Evolution mission to study the upper atmosphere and measure escape rates of gases and ions. The European Space Agency and the Russian Space Agency (Roscosmos) are jointly planning several missions to Mars for the 2016 and 2018 launch opportunities that will deliver a lander and an orbiter in 2016 and a rover in 2018. The 2016 lander is expected to have some meteorological instruments, and the orbiter is expected to monitor trace gases in the atmosphere. Many countries are considering missions to Mars for the decade beginning in 2020 that have atmospheric science in their payloads. A sample return mission continues to be a high priority for many space agencies, and beyond that, human missions will ultimately be attempted. Atmospheric science will benefit from these missions as well.

Table 4 Successful spacecraft missions to Mars since 1996

<i>Mission</i>	<i>Launch date</i>	<i>Type</i>	<i>Status (as of Aug. 2013)</i>
Mars Global Surveyor	07 Nov. 1996	Orbiter	Completed
Pathfinder	04 Dec. 1996	Lander/Rover	Completed
Mars Odyssey	07 Apr. 2001	Orbiter	Ongoing
Mars Express	02 Jun. 2003	Orbiter	Ongoing
MER: Spirit	10 Jun. 2003	Rover	Completed
MER: Opportunity	08 Jul. 2003	Rover	Ongoing
Mars Reconnaissance Orbiter	12 Aug. 2005	Orbiter	Ongoing
Phoenix	04 Aug. 2007	Lander	Completed
Mars Science Laboratory	26 Nov. 2011	Rover	Ongoing

Introduction

Venus is Earth's sister planet, 0.723 times as far from the Sun as is the Earth. Its radius (6052 km) and mass (4.869×10^{24} kg) are 95% and 82% of the Earth's. Thus, in size and distance from the Sun it is quite similar to the Earth, but its atmosphere is strikingly different from the Earth's. The atmosphere of Venus is much more massive, with a mass per square meter of 10.8 kg m^{-2} compared to 0.1 kg m^{-2} on Earth. It is composed of carbon dioxide (96.5% mol fraction) and molecular nitrogen N_2 (3.5%) plus traces of other gases. A hydrosphere is absent on Venus. There is a very low abundance of water in any form. These compositional differences point to a drastically different evolution of the Venusian and terrestrial atmospheres through geological history.

The current state of the Venusian atmosphere also shows great differences from that of the Earth. There is a strong greenhouse effect, which raises the surface temperature to about 735 K (462 °C), despite the fact that cloud cover strongly reflects sunlight so that less heat flux is absorbed on Venus than on Earth. The cloud deck itself is extremely interesting. It is optically thick, and observed from Earth or from space. Venus appears featureless in visible light. The cloud is composed of droplets of a strong solution of sulfuric acid. Its maintenance depends on a cycling of sulfur compounds between the upper atmosphere, where sunlight produces H_2SO_4 by photochemistry, and the lower atmosphere, where high temperatures destroy the acid.

The solid body of Venus rotates very slowly, with a period of 243 days, in the opposite direction to the general rotation of the solar system. The general circulation of the Venus atmosphere is dominated by rotation of the atmosphere in the same direction as that of the solid planet but increasing in speed with height from the surface up to the cloud tops. It reaches maximum speed near the cloud tops, where the rotation period is about 4 days. Atmospheric dynamics are thus very different on Venus and on Earth. Coriolis forces are relatively weak because of slow planetary rotation. Instead, the atmosphere itself develops a rotation by internal mechanisms that are not yet fully understood.

History and Evolution of the Venusian Atmosphere

The total quantity of atmosphere on Venus is known from measurement of surface pressure by probes dropped through the atmosphere. Four of these were flown to Venus by the NASA *Pioneer Venus* spacecraft in 1979, and several were flown by the Russian *Venera* spacecraft program between 1965 and 1985. The surface pressure was found to be about 9.3 MPa.

When divided by the acceleration of gravity (8.87 m s^{-2} on Venus), the pressure yields the atmospheric mass per unit area. Most of this mass is carbon dioxide. On Earth, a similar quantity of carbon is buried in the crust, primarily in the form of carbonate minerals. On the other hand, Earth's oceans contain a total quantity of water equivalent to a layer with basal pressure of a few hundred kilopascals, compared to much smaller traces on Venus. Thus two questions are raised by compositional differences: Why is carbon dioxide on Venus in the atmosphere instead of in crustal minerals as on Earth? Why does Venus have so little water?

Venus and Earth are similar in size and density and are composed of approximately the same array of elements, and are thought to have formed in similar ways during the birth of the solar system. Thus the same inventories of volatile compounds were probably present on both planets at the time of planetary formation. The most abundant of these were water and carbon dioxide. Current differences are thought to be due to evolutionary effects rather than to initial conditions. In particular, Venus is closer to the Sun and the solar flux onto the top of the atmosphere is 1.9 times larger than on Earth. This is thought to have been large enough to push Venus into a runaway greenhouse state, in which water vapor feedback drove the temperature high enough that all water was forced into the atmosphere as vapor or cloud. Water in the upper atmosphere was then exposed to ultraviolet radiation and dissociated. The hydrogen escaped to space and the oxygen was chemically combined with crustal materials; the consequence was rapid loss of most of the initial water inventory.

In the presence of liquid water and relatively low temperatures, carbon dioxide over geological history on Earth has largely precipitated out in the form of carbonates such as calcite (CaCO_3). These Urey reactions remove carbon dioxide from the ocean–atmosphere system. On Venus, the high surface temperature pushes the equilibrium of the Urey reactions toward higher CO_2 pressures. The major portion of the initial inventory of CO_2 on Venus may still reside in the atmosphere.

These ideas regarding the compositional evolution of the Venusian atmosphere remain speculative because of the absence of detailed geological information from the surface of Venus. For example, detailed chemical analysis of surface minerals has not yet been performed, and sedimentary cores such as those used to investigate past epochs on Earth do not exist for Venus.

Thermal State of the Venusian Atmosphere

Figure 1 displays a temperature profile obtained from entry probes. The shape of the profile divides the atmosphere into

Figure 1 Temperature and pressure in the Venusian atmosphere. Measurements are from the *Pioneer Venus* sounder probe, which entered near the equator. The dotted line shows a mean profile for Earth's atmosphere and indicates Earth's surface pressure. Absorption of ultraviolet by ozone on Earth produces a stratospheric temperature maximum with no counterpart on Venus. The approximate location of the Venusian clouds is indicated. Reproduced from Seiff, A., Kirk, D.B., Young, R.E., et al. 1980. Measurements of thermal structure and thermal contrasts in the atmosphere of Venus and related dynamical observations: Results from the four *Pioneer Venus* probes. *Journal of Geophysical Research* 85, 7903–7933.

two regimes. The middle atmosphere is approximately isothermal and is analogous to Earth's middle atmosphere, but without the warm layer due to absorption of ultraviolet solar radiation by ozone on Earth. The lower atmosphere shows temperatures decreasing with height, and is analogous to Earth's troposphere. The heat balance in the middle atmosphere is dominated by heating due to absorption of sunlight in near infrared CO_2 bands and cooling to space from the $15\ \mu\text{m}$ CO_2 band. In the lower atmosphere the heat balance is more complicated and not fully understood. The solar heating is well constrained by direct measurements of solar flux by entry probes. About 76% of the insolation is reflected. The global average absorption is about $F = 157\ \text{W m}^{-2}$, which implies an effective temperature for emission to space of 229 K. Thus the net energy input is smaller than on Earth (where it is approximately $240\ \text{W m}^{-2}$, giving an effective emission temperature of 255 K) because of the high reflectivity of the Venusian cloud deck. More than half of the solar energy is

absorbed in the cloud deck, between heights of about 50 and 70 km. About 10% of the solar absorption is at the planetary surface. The remainder is smoothly distributed gas absorption. The large heat input in the cloud deck, about 60 km, or five scale heights, above the surface, is a very different driver for meteorology compared with that on Earth, where the bulk of the solar heating is near or at the surface.

Thermal radiation flux is less well understood than the solar flux. The high infrared opacity of the major constituent, CO_2 , is important in producing a strong greenhouse effect. But even a small spectral 'window' for leakage of radiation to space can greatly reduce the effectiveness of a greenhouse, and trace gases such as SO_2 and H_2O are important in filling spectral windows on both sides of the $15\ \mu\text{m}$ CO_2 band on Venus. SO_2 , H_2O , and other trace gases are spatially and temporally variable on Venus, and measurements of their distribution are sparse. Furthermore, at the high temperatures and pressures of the lower atmosphere of Venus, the opacities of many gases are not well-known. The spectral distribution of the thermal radiation flux has not been directly measured within the Venusian troposphere. Nevertheless, radiative modeling based on the best estimates of composition has successfully reproduced the Venus greenhouse, and the greenhouse explanation for high surface temperature on Venus is widely accepted.

Four *Pioneer Venus* entry probes measured temperature profiles in 1979, at different latitudes. The profile displayed in Figure 1 was near the equator. The troposphere temperature increases monotonically with depth but the gradient is not uniformly close to the adiabatic gradient. There is a stable layer near 0.3 MPa pressure, and another near 3 MPa. The middle atmosphere, where the pressure is less than 0.03 MPa, is of course also stably stratified. Thus the vertical structure comprises alternating layers, each a scale height or two thick, with nearly adiabatic, low-stability regions within the cloud deck near 0.1 MPa pressure, below the clouds near 2 MPa, and possibly also near the surface. All four of the profiles measured by *Pioneer Venus* showed similar stratification properties. A pair of Russian balloon probes in 1985 gave evidence for strong vertical motions, probably due to convection, in the low-stability layer within the cloud deck. The layered stability structure of the Venusian troposphere is probably important in controlling atmospheric dynamics, but wind measurements are too limited to reveal the effects.

The orbital period of Venus is 224.70 Earth days. Its spin about its axis is in the opposite direction, with a period of 243.02 days. In combination, these motions produce a solar day on Venus of 116.75 days. In spite of this long time, there is very little day–night temperature contrast in the lower atmosphere. A radiative time constant based on the average thermal cooling rate and the entire atmospheric mass is $t_R = c_p p T_M / (gF)$, where c_p is the heat capacity, p is the surface pressure, T_M is the mean atmospheric temperature, g is the acceleration of gravity, and F is the average thermal flux to space. With $c_p = 800\ \text{J kg}^{-1}$, $p = 9.2\ \text{MPa}$, $T_M = 600\ \text{K}$, $g = 8.87\ \text{m s}^{-2}$, and $F = 157\ \text{W m}^{-2}$, one obtains $t_R \sim 100$ years. On the other hand, a radiative time constant based on the atmospheric mass near and above the cloud deck is only a few days, and indeed measurements have shown that thermally driven tides are significant at these heights, with an amplitude of a few kelvins.

There is very little latitudinal temperature contrast in the lower atmosphere of Venus. Here again the large thermal time

constant is probably responsible. As long as dynamical transport times are shorter than the radiative time constant, heat should be well mixed laterally. The situation is probably analogous to that in the deep ocean basins on Earth. Within the clouds, however, there is a latitudinal temperature gradient, cooler toward the poles by about 20 K. At higher elevations the temperature gradient reverses.

Chemical Stability of the Venusian Atmosphere

Above the cloud tops, absorption of solar UV radiation by CO_2 leads to its dissociation into CO and O. Most of the O atoms recombine to form O_2 . The restoration of CO, O, and O_2 back to CO_2 is effected by catalysis involving chlorine atoms derived from the photolysis of trace amounts of HCl in the Venusian atmosphere. The catalytic mechanism is similar to that proposed for the destruction of the terrestrial ozone layer by chlorine atoms derived from anthropogenic chlorofluorocarbons. Chlorine chemistry also catalyzes the oxidation of SO_2 to H_2SO_4 . The essence of the chemical scheme may be summarized as in **Scheme 1**. ClC(O)O_2 is the peroxychloroformyl radical; ClCO is the chloroformyl radical; and M is a third body (ambient atmosphere).

On decadal timescales, the composition of the atmosphere may be subject to perturbations by episodic volcanic eruptions. However, there is no proof that the reported secular variations in SO_2 abundance can be attributed to volcanic processes. It is conceivable that the observed changes are the result of a coupled upper atmosphere and lower atmosphere oscillation (the analog of El Niño in the terrestrial tropical atmosphere). Over geological timescales, both H_2O and SO_2 are unstable. The loss and resupply of these gases might have induced profound climatic changes and could provide an explanation of the tectonic deformations of the crust observed by the *Magellan* mission radar mapping.

The Venusian Clouds

The Venusian clouds are featureless and opaque in the visible light. Absorption in the blue gives the planet a slight overall yellowish tint to the eye. Absorption becomes strong at ultraviolet wavelengths, and also shows contrast that reveals cloud

Scheme 1

Figure 2 Ultraviolet image of Venus from the *Pioneer Venus* orbiter. North is at the top. The general circulation is from east to west (toward the left) and appears to spiral toward the poles. The large-scale dark pattern centered on the image is the 'Y' discussed in the text as a possible traveling wave. Reproduced from Rossow, W.B., Del Genio, A.D., Limaye, S.S., Travis, L.D., 1980. Cloud morphology and motions from *Pioneer Venus* images. *Journal of Geophysical Research* 85, 8107–8128.

patterns. **Figure 2** displays an ultraviolet image taken by the *Pioneer Venus* spacecraft in 1980. The identity of the ultraviolet absorber is unknown, but is most likely polysulfur. The principal component of the cloud is a haze of sulfuric acid droplets of radius about 1 mm. The gaseous precursor of the sulfate particles is SO_2 , but the ultimate source of sulfur is COS from the surface. Once transported to the upper atmosphere, COS is readily oxidized to SO_2 , using the oxygen derived from CO_2 photolysis. The oxidation of SO_2 to H_2SO_4 has been described in the previous section. However, in regions of the atmosphere where O_2 is deficient, COS may be reduced to S_x (polysulfur). Visibility within the haze is a few kilometers. The base of the cloud is at approximately 48 km elevation, where the pressure and temperature are about 0.13 Mpa and 365 K, respectively. Near the cloud base the *Pioneer Venus* probes detected a relatively thin layer, about 2 km deep, containing larger particles and higher number densities than in the main cloud. There is no sharp top to the cloud. The density tapers off gradually between 60 and 75 km elevation. At 65 km the pressure and temperature are about 0.01 Mpa and 245 K, respectively. In addition to their obvious impact on climate, the clouds of Venus have an important effect on atmospheric chemistry. The sulfate particles completely dehydrate the upper atmosphere. The process is analogous to the removal of water vapor by the cold trap at the tropopause of Earth's atmosphere.

The General Circulation

Figure 3 displays wind velocities measured by the four *Pioneer Venus* probes in 1979. Numerous Russian probes have

Figure 3 Wind measurements from drifts of *Pioneer Venus* probes. The east–west component of the velocity is far larger than the south–north component. Vertical shear is smallest at heights where the temperature gradient is closest to adiabatic. Reproduced from Counselman, C.C. III, Gourevich, S.A., King, R.W., Lorient, G.B., Ginsberg, E.S., 1980. Zonal and meridional circulation of the lower atmosphere of Venus determined by radio interferometry. *Journal of Geophysical Research* 85, 8026–8031.

produced similar results. The flow is dominated by an easterly zonal wind increasing with height up to approximately the top of the visible clouds, where it reaches about 100 m s^{-1} . This represents a rotation of the atmosphere in the same direction as that of the solid planet, but with a period of about 4 days within the cloud, about 50 times faster than the rotation of the solid planet. **Figure 3** shows that meridional (south–north) velocities are much smaller than zonal winds in the deep atmosphere.

The falling *Pioneer Venus* probes were only able to measure wind between the surface and about the 65 km level within the clouds. The ultraviolet features shown in **Figure 2** are slightly higher, near the cloud tops, probably at about 65–70 km elevation. Tracking of these features shows zonal motions consistent with probe measurements, but with the advantage that a complete latitudinal profile can be measured. These profiles vary over timescales of a year or so. Sometimes a well-defined high-latitude jet exists, and at other times the profile shows nearly constant angular velocity. The cloud top measurements also show poleward drift with a speed of roughly 10 m s^{-1} in both hemispheres. This may represent the upper branch of a Hadley circulation, and indeed the general appearance of **Figure 2** suggests a flow spiraling toward the poles. The Hadley interpretation may be premature, however, since cloud tracking is not possible on the dark side of the planet and a true zonal mean has not been measured. Solar-fixed tides are known to exist, and may make the dayside measurements unrepresentative of the mean.

The ultraviolet patterns in the Venusian clouds give evidence for large-scale traveling waves. One wave appears in the shape of a ‘Y’ lying over the equator with its base pointed eastward. The branches of the fork in the ‘Y’ merge into the poleward spiral at midlatitudes. The pattern remains coherent

over many rotations and travels with approximately the same velocity as the cloud top circulation. Another wave is occasionally observed at midlatitudes, traveling with a slightly slower velocity. The two waves are thought to be Kelvin and Rossby modes, respectively, but details of their structure and the nature of their excitation are not known.

The Venusian atmosphere is in *cyclostrophic* balance. Coriolis accelerations are weak because the planet rotates slowly. Cyclostrophic balance is the analog of Coriolis balance but with centrifugal replacing Coriolis accelerations. An ideal gas atmosphere in hydrostatic and cyclostrophic balance obeys an analog to the ordinary thermal wind equation of meteorology eqn [1],

$$H \frac{\partial}{\partial z} u_a^2 = -\cot \phi \left[\frac{\partial}{\partial \phi} (RT) \right]_{p \text{ constant}} \quad [1]$$

where the scale height $H = RT/g$, R is the gas constant, z is the height, u_a is the absolute zonal velocity in a nonrotating frame, ϕ is the latitude, and T is the temperature. The latitudinal derivative of temperature is taken at constant pressure. The rotation of the solid planet represents an equatorial velocity of $u_E = 1.8 \text{ m s}^{-1}$, and therefore u_a is the same as u displayed in **Figure 3**, but with a small correction equal to $u_E \cos \phi$. In the deep atmosphere this thermal wind equation can be used to infer temperature gradients from the measured vertical wind shear, and one finds that equator-to-pole contrasts of a few degrees are expected, with the high latitudes cooler. More probes at high latitudes would be necessary to measure this directly. Above the cloud tops, where no direct wind information exists, the measurements of temperature increasing toward the poles indicate that the atmospheric circulation decays with height in the middle atmosphere.

The remarkable spin of the Venusian atmosphere is one of the major puzzles in atmospheric science. In the absence of forcing mechanisms, friction and wave drag would be expected to bring the atmosphere into corotation with the solid planet. Theories fall into two classes. In one, vertically propagating waves transport momentum from the surface into the atmosphere. The waves would need to be selected or sorted by some process, so that those carrying momentum in the direction of the planetary spin are dominant. This explanation is similar to the accepted explanation for the quasibiennial oscillation (QBO) in Earth's stratosphere at low latitudes. The QBO reverses direction approximately every 2 years, however, and, over the 40 years that it has been observed, the direction of the Venus rotation has never reversed.

The other theory relies on a Hadley circulation plus large-scale eddies. The Hadley circulation on Venus is not well measured, but the general appearance of the cloud top circulation suggests that it extends from the equator to high latitudes. Rising motion at low latitudes transports angular momentum upward in such a circulation. Poleward drift in the upper branch leads to the formation of jets at middle and high latitudes. According to the theory, large-scale eddies cause erosion of the jets and act to transfer their angular momentum back toward low latitudes. The joint action of the Hadley circulation and the large-scale eddies can maintain the spin, or superrotation, of the atmosphere. This process has

been successfully simulated with numerical models. Observational test of the theory is not possible at present, however, because data on the Hadley circulation and on eddies are incomplete.

Synopsis

The evidence for influence of solar variability on the climate near the Earth's surface is discussed; the contribution of solar variability to 'global warming' of the past century is very small. Between the troughs and peaks of the '11-year' sunspot cycle the global average temperature varies by perhaps 0.1 °C. This signal is not, however, distributed uniformly across the planet, nor is it concentrated where solar irradiance is greatest – in the tropics, but found in particular regions. Some processes that might produce this pattern are outlined; changes in solar ultraviolet radiation may be the key.

Introduction

Many studies have shown an apparent response in weather or climate indicators to solar variability. At various locations, temperature, rainfall, surface pressure, cloud cover, storms, and droughts, among other meteorological parameters, have been found to correlate with measures of solar activity over the 11-year solar cycle as well as over periods extending from decades to centuries and longer. Some of these studies do not stand up to rigorous statistical analysis, and some appear to hold only over limited time periods, but there is mounting evidence of a solar influence on climate on many timescales. The response of the global average surface temperature is small, being approximately 0.15 °C warmer when the Sun is near maximum activity relative to minimum activity of the solar cycle. This warming does not, however, appear uniformly across the globe so, for example, greater warming is found in middle latitude air temperature while the eastern tropical Pacific Ocean appears to be cooler when the Sun is at peak activity.

The radiant energy output of the Sun varies by about 0.1% over the 11-year cycle which is consistent, using simple radiation balance estimates, with the global mean temperature response. Comparison of solar activity with estimates of global surface temperature back to the Maunder Minimum in sunspot numbers at the end of the seventeenth century suggests that the Sun has made a contribution to climate variability since that time but cannot alone account for the warming of the later half of the twentieth century.

The amount of solar radiation reaching the Earth is also modified by variations in the Earth's orbit around the Sun. These variations take place over periods of tens to hundreds of thousands of years and may be responsible for the occurrence of ice ages.

Variations in other factors than the total amount of solar radiant energy affect the atmosphere and possibly influence weather and climate. Solar ultraviolet (UV) emissions vary by several percent over the solar cycle and influence ozone production and heating of the stratosphere. The chemical structure of the stratosphere is also affected by high-energy protons and electrons emitted during solar flares and coronal mass ejections. Any change in the thermal structure of the stratosphere can influence the climate of the lower atmosphere through dynamical processes and these may contribute

to the nonuniform distribution of the solar signal in surface temperatures.

Alterations in the solar magnetic field affect the flux of galactic cosmic rays (GCRs) reaching the Earth and thus the strength of the Earth's electric field and ionization rates in the lower stratosphere. It is plausible, but unproven, that these result in changes in thunderstorm activity or cloud cover.

Observations

Data Analysis

Variations in the amount of solar radiation reaching the Earth produce the familiar diurnal and seasonal variations, but the effects of changing solar *activity* on weather and climate are much more difficult to observe. The detection of a solar influence on a meteorological record inevitably relies on statistical analysis and an unequivocal identification with the Sun of any derived signal must allow for both the huge natural variability of the climate system, such as associated for example with El Niño–Southern Oscillation (ENSO), and also the possible influence of other factors, such as increases in greenhouse gas concentrations or volcanic eruptions.

One commonly used approach is to investigate time series of data for periodicities associated with solar activity (e.g., around 11, 22, or 80 years). Another simple statistical approach is to estimate the degree of correlation between a meteorological parameter and some measure of solar activity. Again, the main difficulty with these methodologies is the possibility that the natural (unforced) variability of the climate system includes components of the same periodicity. More sophisticated methods explicitly take account of the effects of other influences and/or understanding of the innate statistics of the system (e.g., autocorrelation in time or space).

Influence on Solar Cycle Timescale

The clearest indication of changes in solar activity, noted since ancient times, is the number of sunspots on the solar surface. There are many other indicators, including solar radiation emissions across the electromagnetic spectrum and at specific wavelengths, particularly in the microwave and UV regions. Solar activity is also indicated by the strength of the Sun's magnetic field and in the way it influences the Earth's magnetic

field and the incidence of the GCRs reaching the Earth. The occurrence of solar storms, and the emission by the Sun of high-energy particles, also indicates high levels of activity. All these indicators have been observed to vary cyclically with a period ranging between 9 and 13 years, often referred to as the '11-year cycle'.

The observed amplitude of the solar cycle oscillation in global mean surface temperature is only about 0.15°C , but the geographical distribution is not uniform and larger signals have been observed in some regions of the globe. Cycles of 10–12 year periodicity have been isolated in records including sea surface temperature, surface temperature at many land stations, rainfall in the USA and Africa, surface pressure in the North Atlantic and North Pacific Oceans, North American forest fires, Atlantic tropical cyclones, tropical corals, and the Southern Oscillation.

An example can be seen in **Figure 1** which presents the difference in near-surface air temperature over land, and in sea level pressure, between winters of low and high solar activity in the North Atlantic region. When the Sun is less active, the

Northwest Europe and central Eurasia experience colder winters while Greenland is warmer. The patterns are consistent with the atmosphere tending to be in a more negative phase of the North Atlantic Oscillation at lower solar activity, a signal confirmed by other analyses/datasets.

Another regional response is found in sea surface temperatures where there is evidence that higher levels of solar activity are associated with a La Niña-like signal of cooler temperatures in the eastern tropical Pacific.

Away from the surface, solar cycle signals have been detected throughout the atmosphere, with very large changes, of over 500°C , in the thermosphere and smaller responses at lower altitudes. The tropical upper stratosphere, near 50 km altitude, is around $1\text{--}2^{\circ}\text{C}$ warmer when the Sun is more active. In the polar lower stratosphere in winter, the signal is enhanced significantly when the data are sorted according to the phase of the Quasibiennial Oscillation (QBO), although care has to be taken that the analysis remains statistically sound.

Figure 2 shows the amplitude of the solar cycle signal in temperature throughout the lower atmosphere. The largest

Figure 1 Difference between winters of low and high solar activity (as indicated by value of open magnetic flux) between 1957/1958 and 2000/2001. Colors show difference in near-surface air temperature over land ranging from $+2.0^{\circ}\text{C}$ (dark orange) to -3.5°C (dark blue). Contours show the difference in sea level pressure, the contour interval is 1 hPa and dashed contours represent negative values. Reproduced from Woollings, T., et al. 2010. Enhanced signature of solar variability in Eurasian winter climate. *Geophysical Research Letters* 37: L20805, (<http://dx.doi.org/10.1029/2010GL044601>).

Figure 2 The signal in zonally averaged and deseasonalized temperature ($^{\circ}\text{C}$) found in response to the solar cycle (high minus low solar activity as indicated by the radio flux) over 1979–2002 with the effects of other influences (QBO, ENSO, volcanoes, and long-term climate change) having been removed. Reproduced from Haigh, J.D., 2003. The effects of solar variability on the Earth's climate. *Philosophical Transactions of the Royal Society A* 361: 95–111.

response, of up to 1 °C (solar maximum relative to minimum), is found in the subtropical lower stratosphere with bands of warming, of about 0.4 °C extending through the midlatitude troposphere. This pattern is different from what would be anticipated as a direct response to increased radiative heating and, along with the QBO modulation discussed above, suggests that changes in atmospheric motions play a role in determining the observed solar impact on temperatures.

Decadal-Centennial Scale Influence

The solar cycle fluctuates not only in length but also in amplitude. At 'solar minima' the sunspot number decays to near zero, while at 'solar maxima' it is very variable. At various times in the past, over periods of several decades, sunspot numbers during solar maxima have been observed to become very small – these periods are referred to as Grand Minima. For example, sightings of sunspots were rare over the entire second half of the seventeenth century, an episode now called the Maunder Minimum.

Variations associated with the 11-year cycle are useful for diagnosing signals in local meteorological records, and they can also indicate potential mechanisms whereby the solar impacts are produced, but unless the effects are somehow accumulative they do not imply any long-term influence on climate. On longer timescales, the apparent coincidences of the 'Little Ice Age' from the mid-sixteenth to mid-nineteenth centuries with the Spörer and Maunder solar minima, and of the 'Medieval Warm Period' between about 900 and 1300 with the Medieval solar maximum, have often been cited as inferring a solar influence on global temperatures. More detailed analysis of the temperature signal has revealed, however, that the responses in different geographical regions do not vary synchronously. This makes the link with solar activity ambiguous, and suggests that other factors, including inherent natural variability in the system, must play a part in determining the temporal variation. The 'Little Ice Age' is now viewed as a fairly modest average cooling of the Northern Hemisphere which may be partly ascribed to solar variability, but for which volcanic activity and changes in ocean circulation may also be important.

Long-Term Influence

Estimates of variation in atmospheric temperature over much longer periods may be derived from oxygen isotope ratios in glaciers and ice sheets, lake sediments, ocean sediments, and corals. Spectral analysis of these datasets shows that the dominant component in the record for the last 800 000 years has a period of around 100 000 years. This is of the same order as the periodicity of the eccentricity of the Earth's elliptical orbit around the Sun suggesting a direct solar influence on climate. However, the changes in solar irradiance associated with the variations in eccentricity are too small on their own to explain the observed temperature signal. They are also much smaller than the latitudinal and seasonal deviations in irradiance due to variations in other orbital parameters. These are the tilt of the Earth's axis, which demonstrates a periodicity of 41 000 years, and the precession of the equinoxes, with periodicities of 19 000 and 23 000 years. These periods are less evidenced in

the paleoclimate records indicating that other factors than simply the instantaneous total solar irradiance contribute to the long-term solar influence on climate.

Mechanisms for Solar–Climate Interaction

On the long timescales a key factor is the change in the seasonal intensity of solar radiation. For example, if increased summer irradiance is insufficient to melt the extended ice sheet resulting from a colder winter, then the climate system may be propelled into an ice age. Current General Circulation Models (GCMs) are not able to reproduce ice sheet growth suggesting that the representation of the processes may be incomplete (feedbacks involving vegetation cover and type may be an example) or that nonlinear interactions between the different processes are not properly included.

On solar cycle and decadal–centennial timescales, the observational analyses described above provide evidence for an influence of solar variability on climate but, without a clear understanding of the mechanism(s) through which such interactions take place, doubts may remain that the periodicities and correlations found are due to natural internal atmospheric variability or to other climate forcing factors. The most direct means whereby solar variability may affect climate is through modulation of the total solar radiative energy received by the Earth. Other, more indirect, means might be through modification of atmospheric chemical composition or of the Earth's electric field or of cloud formation.

Radiation Balance

The total radiative power emitted by the Sun crossing unit area at the Earth's mean orbital distance is approximately 1361 W m^{-2} , although differences in absolute calibration of the spaceborne radiometers mean this value is uncertain to a few watts per square meters. Historically, this was referred to as the 'solar constant' because it was believed not to vary but measurements made from satellites since the late 1970s have shown that total solar irradiance (TSI) changes by about 1.4 W m^{-2} , or 0.1%, over the 11-year cycle with higher values corresponding to periods of greater solar activity as indicated by sunspot numbers. Based on these measurements, and on historical observations of an indicator of solar activity such as sunspot number, it is possible to estimate values of TSI in the past. In doing this, however, it is also necessary to make some assumption about the slowly varying change in solar activity which underlies the 11-year cycles known and is known as the quiet Sun. There is considerable uncertainty in the magnitude of this component so that recent estimates of the difference in TSI between the late seventeenth century (during the Maunder Minimum in solar activity) and the present range from about 1.3 to 6.5 W m^{-2} .

The equilibrium change in global average surface temperature, T_s , due to a change in the Earth's radiation balance may be estimated from the expression $\Delta T_s = \lambda \Delta F$, where ΔF is the imbalance in global average radiative fluxes and λ a climate sensitivity parameter which represents the response of the surface temperature to applied radiative perturbations, taking into account atmospheric feedback mechanisms through, changes in humidity

or cloud cover. λ is estimated from atmosphere–ocean GCMs to be about $0.625 \text{ K W}^{-1} \text{ m}^{-2}$. An increase in TSI in the range of $1.3\text{--}6.5 \text{ W m}^{-2}$, since the Maunder Minimum, corresponds to a change in radiative flux ΔF of $0.23\text{--}1.14 \text{ W m}^{-2}$ taking account of global averaging and terrestrial *albedo*. Using the climate sensitivity value above this would suggest, using the expression above, a surface warming in the range of $0.14\text{--}0.71 \text{ K}$ due to the Sun since about 1700. The observed overall rise in temperature over that period is about 0.7 K , so the range in TSI might suggest that anything between one-fifth and all global warming is due to the Sun. The larger value is very unlikely, however, as it would pose two inconsistencies: (1) temperature variations in response to solar activity over earlier times should have been much larger, and (2) the evolution of the temperature variation since 1700 should correlate better with the TSI reconstruction. Clearly, more work is needed to establish the historical variations in TSI as well

as to advance understanding of the physical processes in the Sun that produces them.

Another problem associated with simply associating changes in temperature with differences in TSI is the neglect of other potential factors. One attempt to distinguish these in global mean surface temperature over the past century is portrayed in Figure 3. This shows, by the black curve in panel (a), the time series of the temperature measurements together with, in the other panels, those of the factors assumed to be contributing: ENSO, volcanic aerosols, solar irradiance, and human activities (mainly greenhouse gas emissions and industrial aerosol production). The amplitudes (as opposed to the temporal variations) of the contributions are not specified in advance but are determined by a statistical analysis which produces the best fit to the observed temperature data. The sum of the deduced contributions is portrayed by the orange curve in panel (a).

Figure 3 Global mean near-surface temperature 1889–2008 (a) from observational records (black) and reconstructed (orange) from the components associated with (b) ENSO, (c) volcanic aerosols, (d) solar irradiance, and (e) human activity. Reproduced from Lean, J.L., 2010. Cycles and trends in solar irradiance and climate. Wiley Interdisciplinary Reviews: Climate Change 1: 111–122, <http://dx.doi.org/10.1002/WCC.18>.

The 11-year cycle in irradiance makes a small contribution to the temperature variations while the underlying secular increase in irradiance over the first half of the century appears to contribute about one-third of the upward trend in temperature over that period. The Sun does not contribute to global warming over the later half of the century. The solar irradiance curve in panel (d) of Figure 3 is one which possesses an underlying trend (relative to the 11-year cycle amplitude) at the low end of current estimates but no reasonable reconstruction of solar irradiance over this period, however, can account for the significant warming of the past half century.

The La Niña-like signal, outlined above, of cooler sea surface temperatures in the tropical Pacific associated with higher levels of solar activity, may be associated with the variation in TSI. Differential heating of the sea surface between cloudy and clear regions might induce a change in surface wind stress and thus in the meridional overturning circulation of the upper ocean. Further work needs to be done, however, to definitively extract a solar signal, given the large innate variations in sea surface temperature related to ENSO.

UV

The variability in TSI, discussed above, of a few tenths of 1% represents the change integrated across the whole electromagnetic spectrum. Measurements made by satellite instruments, and also the results of theoretical models, show much larger fractional changes in the UV radiation which is absorbed higher in the atmosphere.

Most of the visible/near-infrared radiation passes through the atmosphere unhindered to the tropopause. Water vapor bands in the near-infrared cause some absorption in the lower troposphere, and some radiation is scattered by cloud, but most of this radiation reaches the surface. Shorter (UV) wavelengths, however, are absorbed higher in the atmosphere where they cause local heating and ozone production. The increased ozone tends to mask the lower atmosphere from the enhanced incident UV while the warmer stratosphere will cause increased emission of thermal infrared (TIR) radiation. Thus the changes in the UV and TIR radiations reaching the troposphere depend on the variations in ozone. However, the response of ozone to solar activity is not very well established. Multiple regression analysis of satellite ozone measurements suggests largest changes in the upper and lower stratosphere and a much smaller change in the middle stratosphere. However, the data are available only for about two solar cycles and have large uncertainties, especially in the lower stratosphere. Furthermore, it is difficult to extract a 'pure' solar signal separately from the influence of volcanic eruptions and ENSO. Coupled chemistry climate models have limited success in reproducing the signal extracted from the satellite record, and generally do better if variations in sea surface temperatures are included, possibly due to the mixing of the solar signal with ENSO.

Changes in stratospheric thermal structure may also affect the troposphere through dynamical interactions rather than through radiative forcing. Studies using computer models have shown that variations in solar UV radiation, which primarily heats the stratosphere, produce regions of preferred response to

solar activity in the troposphere and at the surface. These are produced by dynamical adjustments within the atmosphere, i.e., changes in winds and circulation patterns, rather than by direct radiative heating. Several such studies have reported a solar signal in the strength and extent of the tropical overturning circulations (Hadley and Walker cells) and in the positions of the middle latitude storm tracks. They also suggest that at higher solar activity, the circulation tends to favor more positive phases of the Northern and Southern Annular Modes. These responses are consistent with some of the observed signals at the surface, outlined earlier in this article, which shows a geographically nonuniform response to variations in solar input, with surface temperatures at some locations showing heating and some cooling during periods of higher solar activity.

Solar Energetic Particles and GCRs

Solar storms and flares occur more frequently during periods of higher solar activity. As a result of these events, high-energy particles (protons, electrons, and alpha particles) are ejected. These can enter the Earth's atmosphere along the open magnetic field lines near the polar caps. Particles with energies of $> \sim 10$ MeV penetrate down to the middle atmosphere where they cause an increase in the concentration of nitrogen oxides through ionization and dissociation of N_2 and O_2 . The NO produced can cause significant reduction in middle atmosphere ozone concentrations. Higher energy particles can penetrate deeper into the atmosphere and to lower latitudes. Although individual solar particle events only last on the order of a few hours the chemical perturbations may persist for several months, propagating downward and equatorward and possibly altering stratospheric dynamics. The climate impact of this is likely to be small but has not been studied in detail.

GCRs are particles that are formed outside of the solar system and bombard it from all directions. The flux of GCRs reaching the Earth is modulated by interaction with magnetic structures advected with the solar wind such that at times of higher solar activity the GCR flux is reduced by about 20% with respect to periods of lower solar activity. The flux into the atmosphere is also affected by the Earth's magnetic field such that it is greater at higher latitudes. The GCRs which do penetrate the atmosphere are a major source of ionization, particularly in the lower stratosphere.

There are two main theories advanced as to the means whereby variations in GCR flux might impact climate. The first concerns modulation of the Earth's electric field. Ionization of the atmosphere by GCRs, or indeed by solar energetic particles, will influence its conductivity and thus the current flow within the Earth's electric circuit. It is possible that the current flow into clouds affects cloud microphysics, ice formation, and hence thunderstorm activity, although details of this mechanism are not fully established. While GCRs are more prevalent during periods of minimum solar activity, solar energetic particles are more numerous at solar maximum so that their combined effect over the solar cycle is not clear.

The second means whereby it is proposed that GCRs may affect climate is through enhancing the production of cloud

condensation nuclei through growth of aerosol on ionized air molecules. Some evidence for the existence of this process has been obtained in observational and modeling studies, although not clearly in response to solar activity.

Introduction

The Sun is losing mass in form of the solar wind, which has affected its evolution from its birth and will continue to do so until its death. This is not unusual, in that nearly all stars are losing mass through stellar winds throughout a major portion of their lives. As far as the Earth is concerned, the solar wind blows against the Earth's magnetosphere, causing auroras and geomagnetic storms.

The Corona

The surface of the Sun is called the photosphere, above which lies the Sun's atmosphere, known as the corona. The solar wind forms in the corona and is caused by high pressure in the corona relative to the low pressure far from the Sun in the interstellar medium. This pressure gradient exerts an outward force against gravity and accelerates the wind from low speeds in the low corona up to supersonic speeds at 2–10 solar radii ($R_{\odot}$). To give a sense of scale, the Earth is 1.5×10^8 km = $215R_{\odot}$ from the Sun (defined as 1 astronomical unit or 1 AU). Typical solar wind speeds beyond $10R_{\odot}$ are between 300 and 800 km s⁻¹ so it takes the solar wind 2.2 to 5.8 days to reach Earth. The existence of the solar wind was inferred prior to the space age from the existence of auroras, disturbances to the Earth's magnetosphere, and observations of comet tails. Today it is regularly observed with a number of spacecraft.

Coronal Expansion

Pressure in the corona is high because the temperature is high, more than 10^6 K, relative to the photospheric temperature of ~ 5800 K. This is a sufficiently high temperature that the corona emits copious X-rays. It is believed that the corona is heated to this high temperature as a by-product of magnetic field motions, interactions, and instabilities in the photosphere that directly transfer energy into the corona. This energy flux could be via direct heating, waves, jets of material, or other forms, but this is unknown and is the subject of research by several different observatories in space and a deep-space mission called Solar Probe that will travel to within $3R_{\odot}$ of the photosphere.

The corona is composed mainly of protons and electrons (ionized hydrogen), with minor amounts of silicon, carbon, iron, oxygen, and other elements. There is about 20% helium (by mass) that can be observed spectroscopically; this is how helium was first discovered – hence its name (after *Helios*, the Sun god of Greek mythology). All the components share in the expansion of the corona and can be measured *in situ* by spacecraft outside the Earth's magnetosphere.

The Sun's magnetic field makes the solar wind far from a simple spherical expansion of a hot gas. The magnetic field is dipole-like but undergoes a reversal during every 11-year solar sunspot cycle. At sunspot minimum the field is aligned with the solar rotation axis, while at solar maximum many sunspots appear and the dipole field weakens and becomes irregular. From solar maximum to minimum the field again becomes dipolar, but is inclined relative to the rotation axis. These changes are reflected in changes in coronal structure, which can be seen during solar eclipses such as that shown in [Figure 1](#). With the bright disk of the Sun being occulted by the moon, the faint corona becomes visible, primarily because of light coming from the photosphere being reflected off of electrons in the corona. The areas that are bright are regions of high density and are known as streamers. The dark regions at the top and bottom in [Figure 1](#) are coronal holes. The streamers in [Figure 1](#) lie over the magnetic equator and the density is higher because ions and electrons are trapped on closed loops of the dipolar magnetic field. The low-density coronal holes mark the locations of the north and south magnetic poles. [Figure 1](#) was taken in 1994, just prior to solar minimum, so that the magnetic axis was only slightly inclined to the rotational axis, which is vertical in this image.

[Figure 2](#) is a schematic of the stages of coronal evolution over the 11-year sunspot cycle, starting at solar maximum on the left. [Figure 1](#) is represented by the drawing in [Figure 2\(c\)](#). The magnetic field loops in streamers are shown here to help suggest why the ions and electrons are trapped, just as iron filings tend to align along magnetic field lines around a bar magnet. Coronal holes are shown by the dark areas on the solar disk. This figure also indicates that fast solar wind originates from coronal holes and slow solar wind from above streamers. Fast solar wind has speeds above ~ 600 km s⁻¹ at 1 AU and slow solar wind has speeds below ~ 500 km s⁻¹. This division

Figure 2 Schematic illustration of the three stages in the 11-year solar sunspot cycle. (a) Solar maximum, when the corona is filled with streamers and there are few or no coronal holes. There is no well-defined large-scale field. (b) Declining phases when the large-scale field is dipole-like and inclined to the heliographic equator. (c) Solar minimum when the field is dipolar, aligned with the rotation axis, and when the polar coronal holes are largest.

into fast and slow wind could be observed if one were able to pass around the Sun as shown in Figure 2(c) from south pole to north pole. It would then be possible to sample first fast wind from the south pole, slow wind from over the equatorial streamers, and then fast wind again from the north pole. The *Ulysses* spacecraft carried out this exercise in 1995–1996 at solar sunspot minimum and a plot of the observed solar wind speed is shown in Figure 3 using what is called a dial plot. The dial

Figure 3 Dial plot of solar wind speed, indicated by radial distance from the origin, as a function of heliographic latitude, measured around the origin of the plot. Data were collected by the *Ulysses* solar wind plasma instrument between September 1994 and July 1995, during which time *Ulysses* swept from 80° south latitude to 80° north latitude.

plot indicates the solar latitude around the origin and the measured solar wind speed as distance from the origin. The fast wind in the north and south is very clearly divided from the slow wind above the equatorial streamers in this plot. This demonstrates one of the major discoveries in recent years — that fast and slow solar wind represent two distinct states between which there is no continuous change. Fast wind comes from coronal holes and is rather smooth and uniform at 1 AU. Conversely, slow wind is relatively irregular and comes either from thin boundaries around streamers or leaks somehow from within streamers. Figure 4 shows profiles of how fast and slow wind vary with distance from the Sun, illustrating not only that the speeds are different but also that there are characteristic densities and temperatures differences. T_e and T_p are the proton and electron temperatures in this plot. The distinct difference between the two solar wind states leads to important consequences because of solar rotation.

Solar Rotation and the Magnetic Field in the Solar Wind

Solar wind is an ionized gas made up primarily of protons and electrons with minor ions in amounts similar to those in the corona. The electrons and ions are very tightly bound to lines of magnetic flux, again like the coronal plasma in streamers. However, the magnetic field in the solar wind is relatively weak and thus is carried along by the solar wind. The rotation of the Sun results in the lines of magnetic flux in the solar wind being drawn into Archimedean spirals. This occurs because the Sun revolves once every ~ 25.5 days while, as mentioned above, it takes solar wind several days to reach 1 AU. Therefore, the Sun revolves through a significant angle during the time it takes the solar wind to reach the Earth. For example, taking a typical speed of 400 km s^{-1} , it takes solar wind 4.34 days to reach 1 AU. During the same time, the Sun will have revolved through about 60° , or about $1/6$ of a full rotation. The magnetic field in the solar wind, called the interplanetary magnetic field, or IMF, is attached to the Sun at the point where the solar wind began. Thus, the point on the field line attached to the Sun is turned through an angle of 60° relative to the point on the magnetic field line that is at 1 AU. The field line between the Sun and 1

Figure 4 Solar wind flow speed, density, and temperature between $2R_S$ and $100R_S$, for coronal holes (yellow lines) and streamers (black lines). These are typical values, with the possible range around these values being quite large.

AU traces a continuous curve between these two points. Assuming the solar wind speed, v (km s^{-1}), is independent of distance from the Sun, this curve is described by eqn [1].

$$r - r_0 = \frac{-v}{\Omega \cos \theta} (\phi - \phi_0) \quad [1]$$

In eqn [1], r is the distance from the center of the Sun in km, $r_0 = 6.96 \times 10^5$ km is the radius of the Sun, $\Omega = 2.85 \times 10^{-6} \text{s}^{-1}$ is the angular velocity of the sun, and $(\phi - \phi_0)$ is the difference in longitude (in radians) at the two points on the field line. θ is solar latitude and the Earth lies in the range $-7.25 < \theta < 7.25$ degrees because the plane of the ecliptic is inclined to the solar equator by 7.25° . The angle $(\phi - \phi_0)$ is also the angle between the magnetic field line and the radial direction at 1 AU, or wherever eqn [1] is evaluated. This is called the spiral angle. The geometry of the curved field line is precisely an Archimedean spiral when v is constant and this is one of the important predictions made by E. Parker when he developed his theory for the solar wind in the 1950s and 1960s. Figure 5 illustrates two spirals computed using eqn [1]. The tighter spiral above results from low speeds, $< 500 \text{ km s}^{-1}$, and the spiral angle is $> 45^\circ$ at 1 AU. Conversely, the spiral angle at 1 AU is $< 45^\circ$ for speeds $> 500 \text{ km s}^{-1}$. Parker predicted that $(\phi - \phi_0) \sim 45^\circ$ (0.785 radians) at 1 AU and this is what has been measured for the average spiral angle by several different spacecraft.

Figure 5 Diagram of spiraling interplanetary magnetic field (IMF) lines. The dependence on solar wind speed is illustrated by the more curved line at the top being for relatively slow wind and the less curved line at the bottom being for fast wind.

Corotating Interaction Regions

Solar rotation has an important effect on coronal expansion through the interaction of fast and slow wind. During the declining phases of the solar cycle, (Figure 2(b)), regions on the Sun producing slow wind will sometimes face the Earth and at other times regions producing fast wind will face the Earth. Thus it will often be the case, especially during declining phases of the solar cycle, that slow wind will be followed by fast wind. This is just the example diagrammed in Figure 5. When this happens, fast wind overtakes slow wind, the gas in between becomes compressed, and eventually shocks form with forward shocks moving away from the Sun and reverse shocks moving toward the Sun in the frame of reference moving with the solar wind. This is called a corotating interaction region (CIR) because it appears stationary in the frame of reference rotating with the Sun. As the plasma between the fast and slow wind becomes compressed, the velocity profile is dynamically altered and the CIR becomes stronger and stronger with increasing distance until the shock forms. A simple estimate for where the shocks will form can be made using eqn [2], where the same definitions are used as in eqn [1].

$$r - r_0 = \frac{v_1 v_2}{v_2 - v_1} \frac{(\phi_2 - \phi_1)}{\Omega \cos \theta} \quad [2]$$

The quantity $(\phi_2 - \phi_1)$ is the difference in longitude of the source regions of fast and slow wind, v_1 and v_2 are the slow and fast wind speeds, respectively, and r is the estimated distance for shock formation. Taking $(\phi_2 - \phi_1) = 0.53$ radians $= 30^\circ$, $v_1 = 400 \text{ km s}^{-1}$, and $v_2 = 800 \text{ km s}^{-1}$ gives $r = 1.5 \times 10^8 \text{ km} = 1 \text{ AU}$. During the declining phases of the solar cycle it is observed that shocks generally form around 2 AU, which is consistent with eqn [2] since $(\phi_2 - \phi_1)$ is more nearly 1 radian than 0.5 radians at those times. Forward shocks are rarely observed at 1 AU and reverse shocks are only observed in $\sim 20\%$ of CIRs at 1 AU. Equation [2] was derived simply by calculating when the two field lines shown in Figure 5 would cross. These field lines are the same as the streamlines in the frame of reference corotating with the Sun, and this is why eqn [2] looks closely related to eqn [1].

Figure 6 Solar wind speed at *Ulysses* during August–December 1992 when *Ulysses* was near the heliographic equator and at ~ 5 AU. Five corotating interaction regions (CIRs) are shown, occurring approximately every 25.5 days, or each solar rotation. Viewing the plot from left to right, each CIR is characterized by a sharp speed increases at forward and reverse shocks at the front of the CIR, followed by the speed maximum. The speed then decreases to a minimum before increasing in the next CIR. The very high speed on 10 November 1992 is due to a coronal mass ejection on top of the CIR.

CIRs have a very distinctive character, as seen in the long series of CIRs observed by *Ulysses* in 1992 when it was near the Sun's equator. About five solar rotations of the data are shown in [Figure 6](#). At the time *Ulysses* was at ~ 4 AU and fast wind had overtaken slow wind to form shocks where the speed is seen to abruptly jump upward as time progresses from left to right. CIRs have important consequences for the Earth since they can produce auroral activity and magnetic storms when they strike the Earth's magnetosphere if the IMF is also directed southward so that it can easily merge with the Earth's magnetic field. CIR-associated magnetic storms naturally tend to recur every solar rotation – 27 days as viewed from the Earth owing to the Earth's motion around the Sun. This activity also has a distinct solar cycle signature as the Sun moves through the phases diagrammed in [Figure 2](#). Thus, observation of coronal holes and streamers and the phase of the solar cycle provides a basic tool for the prediction of space weather and geomagnetic activity. A further consequence of CIRs is that the resulting shock waves produce large numbers of high-energy particles or cosmic rays. These particles affect the Earth's ionosphere and the radio communications that depend on the ionosphere.

Coronal Mass Ejections

Up to this point, a picture of the solar wind has been drawn that depicts it as quasi-steady, changing only slowly over the 11-year solar sunspot cycle. This is not an accurate picture at any time, especially near solar maximum. There are many forms of solar activity, including flares and erupting prominences, but the most dramatic is the release of a coronal mass ejection, or CME. A picture of a CME is shown in [Figure 7](#). This picture was taken from the SOHO spacecraft using a telescope called LASCO, which places an occulter over the solar disk so that the corona becomes visible, producing an artificial solar eclipse. The occulter is twice the size of the Sun, and the disk of the Sun is indicated by the white circle. Off to the lower right of the image is the CME. These are seen throughout the entire

Figure 7 A coronal mass ejection is seen in the lower right quadrant in this image from the LASCO coronagraph on SOHO. The Sun, which is covered by an occulter that is $4R_{\odot}$ in diameter, is indicated by the white circle.

solar cycle, but they are 5–10 times more common near solar maximum, occurring at a rate of 3–4 per day. They occur in and near streamers, confined to low latitudes near solar minimum but reaching all latitudes at solar maximum.

When an interplanetary CME (ICME) strikes the Earth, the consequences are similar to those of a large CIR. The magnetosphere is compressed, auroral activity increases, and a magnetic storm or substorm may occur if the IMF in the ICME is directed southward. Ionospheric activity is also affected. This is therefore a phenomenon that is actively monitored in the context of space weather.

One CME is visible in the data shown in [Figure 6](#). At about 10 November 1992 the solar wind speed increased to ~ 1000 km s^{-1} . This is above any speed for simple fast solar wind. Instead, what is seen here is a fast ICME that has overridden a CIR. This could have a doubly strong impact on the magnetosphere owing to the large speed enhancement.

ICMEs are another phenomenon in the solar wind that is only partially understood. The propagation of an ICME can be modeled fairly well using computers and a numerical solution of the equations of motion. However, the basic mechanisms causing the initiation of a CME are not known. CMEs are related to solar magnetic activity such as flares and erupting prominences, but that relationship is not so simple that one can predict a CME for anything except the very largest of these events.

The Solar Wind over the Life of the Sun

The IMF is not completely passive in the solar wind. Because it is attached to the Sun, and has a small, but finite strength, the IMF tends to cause the solar wind to rotate with the Sun out to some distance above the photosphere. In doing this, the IMF causes angular momentum of the Sun to be transferred to the solar wind. Generally this is a small effect, with the corotation distance being $10\text{--}20R_{\odot}$ at most, or 0.1 AU. However, over the life of the Sun, the effect can be important. Calculations of the angular momentum transfer suggest that the present-day solar

wind and IMF could easily have doubled the rotation period of the Sun, from 12.25 to 25.5 days, over the 4.5 billion year life of the Sun.

Presently the solar wind carries away only a very small amount of mass from the Sun – so small that if assumed the same for 4.5 billion years it would have removed only $\sim 0.01\%$ of the total mass of the Sun. However, the Sun changes over its life, as do all stars. The Sun probably had a very vigorous wind early in its life when the solar convection zone extended throughout the entire volume of the Sun. Later in its life the Sun will go through a red giant phase, expanding outward to envelop the Earth, and the wind may again become quite strong. If the Sun undergoes a catastrophic collapse to form a white dwarf then there may be one or several episodes of impulsive mass ejection called novae. However, the Sun is a relatively small and inactive star; other stars can have quite different and often far more intense winds.

Winds from Other Stars

Stellar winds are, as indicated above, common. One means by which they are detected and analyzed is through Doppler shifts in spectral lines. Another is to infer the presence of the wind through analysis of properties of the associated star. Stellar winds found this way are all far stronger than the solar wind, but the reader should be cautioned that this is an observational selection effect. The Sun's wind would be invisible at stellar distances. If all stars were like the Sun, we would presently have no way to directly detect their winds. However, many stars are larger, hotter, denser, rotate faster, have stronger magnetic fields, are younger, or are older than the Sun and consequently have quite different kinds of winds. They fall into several categories that are in addition to winds like the solar wind that are primarily driven by a thermal pressure gradient.

Sound Wave-Driven Winds

In stars with a convection zone just below the photosphere, the convective motions can generate acoustic waves that propagate upwards through the photosphere. The waves produce a wave pressure in the atmosphere that results in an additional force working against the stellar gravity. Cool stars have convection zones of this type but the phenomenon is normally important only for very low-gravity stars. To make a massive wind requires something else in addition to sound waves because sound waves will normally dissipate low in the stellar atmosphere. The dissipation of sound waves heats the atmosphere so that there can be some crossover between thermally driven winds and sound wave-driven winds.

Dust-Driven Winds

The outer atmospheres of luminous cool giant stars and early type stars can be driven outward by radiation coming from the photosphere of the star. In the case of cool stars, dust can condense out of the atmosphere and absorb photons over a broad range of wavelengths. The radiation pressure forces the grains outward, dragging ions along by viscous drag if the atmosphere is dense, thus forming a dust-driven wind.

Alfvén Wave-Driven Winds

Alfvén waves are waves dominated by fluctuations transverse to the magnetic field direction. The restoring force is the resistance of the magnetic field to forming a kink, as opposed to the resistance of a gas to being compressed in sound waves. These waves are more important for stars with stronger magnetic fields. The dissipation of energy and momentum associated with Alfvén waves can lead to the acceleration of a wind, just as in sound wave-driven winds. The waves are formed by motions in the photosphere causing the magnetic field line to be moved. Alfvén waves have been suggested to be one source of the energy flux driving the solar wind. However, it is not yet known whether this is the dominant energy source. The dissipation of Alfvén waves will heat the atmosphere and increase the thermal pressure so that there is also some crossover between thermally driven winds and Alfvén wave-driven winds.

Radiation Pressure-Driven Winds

In these winds, atoms in the atmosphere of the star resonantly absorb radiation coming from the photosphere of the star. As might be expected, these winds exist for stars that are brighter and hotter than the Sun. Instead of 10^{-4} solar masses being lost over the life of the star, these stars can lose 10^{-6} solar masses in a single year. The flow speeds are typically $\sim 2000 \text{ km s}^{-1}$ and the density in these winds is many orders of magnitude higher than in the solar wind. The higher density means that the atmospheres of these stars are far more opaque than the solar corona. This is what enables them to absorb the radiation coming from the star. In this case the radiation pressure is the force that is working against the gravitational field of the star. The force ceases once the atmosphere becomes transparent as distance from the star increases. In red giant stars the radiation intensity is relatively weak, but the gravitational field is also weak and the stars are nevertheless observed to have radiatively driven winds. However, the strongest radiatively driven winds come from hot supergiants.

Magnetic Rotator Winds

In discussing the solar wind over the lifetime of the Sun we described how the magnetic field enhances the loss of angular momentum from the Sun by causing the ions and electrons to rotate together with the Sun as they move outward. At the same time, there is also a small outward centrifugal force, just as there is in a centrifuge. This force is completely negligible for the Sun, but one can imagine stars with stronger magnetic fields that might have centrifugally driven winds; these are called magnetic rotator winds.

The most obvious example of a magnetic rotator wind is that from a neutron star. These stars have very strong magnetic fields and centrifugal forces fill the neutron star magnetosphere with charged particles. At some distance from the star, the azimuthal velocity of the charged particles, as they are carried around the star, reaches the speed of light. The surface at this distance is the 'speed of light cylinder' and somewhere in this region around the star the particles force the field lines to open and they are released. This is how a pulsar is formed, an extreme example of a magnetic rotator.

Effects of Winds on Stellar Evolution and on the Surrounding Interstellar Medium

Winds from stars are one way in which matter that has been processed in stellar interiors reaches the interstellar medium and becomes available for new star formation; the other way is via novae and supernovae. The composition of the wind reflects, but may not be identical to, the composition of the star. Primordial material will be processed and enriched in heavy elements in this process.

The solar wind serves as an example of this process, even though the wind is relatively weak. The wind moves outward to interact with interstellar material that is always present in the galaxy. There is a contact surface that divides interstellar material from solar wind and the volume inside this surface is known as the heliosphere – that volume dominated by the Sun. The solar system is moving through the local interstellar medium at $\sim 25 \text{ km s}^{-1}$ – slow with respect to solar wind speeds – and the stand-off distance in the upstream direction is about 150 AU. Beyond this boundary lies pristine interstellar matter. In the downstream direction the solar wind flows into a heliotail that is analogous to the Earth's magnetotail and is the path by which the solar wind escapes and mixes with interstellar matter.

Nomenclature of Sources and Sinks

The Earth's upper atmosphere is continuously being bombarded by solid objects from interplanetary space. Their constituents may have provided prebiotic organic molecules for the origin of life, and even today this influx of solid particles is responsible for the continuous replenishment of a layer of metal atoms at an altitude of between 80 and 110 km. Even the smallest grains are precious momenta of the origin of the solar system and trace the dynamical processes of formation and disintegration of the first kilometer-sized planetesimals called comets and asteroids, from which they originate. The daily influx of meteoroids is the more relevant for most studies of atmospheric chemistry and physics. The much more dramatic, but rare, impacts of comets and asteroids will not be discussed here.

Meteoroids, also called interplanetary dust particles, carry much kinetic energy, about 1% of which is converted to visible light in collisions with air molecules, creating the transient phenomenon called a meteor. This energy and momentum transfer results in atmospheric chemistry and meteoroid ablation, and leaves behind a range of atomic, molecular, and solid particle products.

The following products have been identified in Earth's atmosphere. Meteor trains of enhanced densities of electrons, oxygen atoms, and meteoric metal atoms are routinely observed by radar, lidar, and other remote sensing techniques. Meteoric neutral metal atoms are the source of the sodium airglow emission and form a layer between about 80 and 110 km, called the neutral atom debris layer. These metal atoms can chemically react and condense into nanometer-sized solid particles called recondensed meteoric vapor. There is indirect evidence that nanometer-sized solid particles reside at altitudes of 70–85 km, where they act as nucleation sites for water vapor to form noctilucent clouds and are a source of weakly bound electrons. Larger solid particles, of size 10–100 μm , that survive the ablation process are called meteoric debris and have been collected in the stratosphere and at Earth's surface. Small, nanometer-sized meteoric matter with chondritic abundances has been detected as a contaminant in (or nucleation site of) larger sulfuric aerosols in the stratosphere.

If the meteoroids are sufficiently small ($<50 \mu\text{m}$) and come in slow enough ($<20 \text{ km s}^{-1}$), and if they are large enough to effectively radiate the heat ($>10 \mu\text{m}$), then they may survive the heating process almost intact. These particles are collected in the stratosphere and are called Brownlee particles, interplanetary dust particles, or micrometeorites. They are also collected in sediments on Earth's surface, where they are called exclusively micrometeorites. Micrometeorites tend to have an asteroidal origin, like the larger meteorites, because cometary material tends to be more fragile and enter Earth's atmosphere at higher speed and therefore tends to not survive the ablation process.

Annual and Daily Variation of Meteoroid Influx

The daily influx of extraterrestrial matter (Figure 1) is dominated by particles of size 100–200 μm , to the amount of $4 \times 10^7 \text{ kg yr}^{-1}$ (for sizes up to 300 μm). These meteoroids have a mean impact velocity of 25 km s^{-1} , but with a wide range from 11 to 72 km s^{-1} . Depending on the latitude of the observing site, most cometary matter in retrograde orbits and the dust particles of the zodiacal cloud that have nearly circular orbits are accreted in the morning hours, between 3.00 and 6.00 a.m. local time (the apex source), when the direction of Earth's motion is highest in the sky. For the same reason, the annual variation of meteor rates tends to peak in autumn on the Northern Hemisphere. On the other hand, the fall of meteorites and micrometeorites peaks in the afternoon hours because of the predominantly prograde orbit of the asteroidal matter and the low encounter speed needed for survival of this material (Figure 2).

The daily sporadic influx is interrupted by meteor showers, which are significant especially for relatively large meteoroids that cause visible meteors (10^{-5} g to 10^3 g). Most well-known

Figure 1 Overview of the influx of extraterrestrial matter in Earth's atmosphere and the nomenclature for sources, phenomena, and products. Strength of 4 m peak is uncertain.

Figure 2 Typical variation of annual meteor shower activity. The asymmetry is the result of a gradually precessing orbit.

examples are the Perseid shower in summer and the Geminid and Quadrantid showers in winter (Table 1). Meteor showers are caused by dust grains released from comets, which all still approach Earth on nearly parallel orbits from a direction called the shower radiant (RA, DEC in Table 1). Unlike the sporadic background, the meteor shower size distribution is not collisionally equilibrated. Most mass is in the larger grains, which replenish the population of smaller meteoroids. The number distribution index $r = N(m+1)/N(m)$ tends to be lower than those of the sporadic background. r relates to the size distribution index: $s = 1 + 2.5 \lg r$.

During annual meteor showers, rates vary over time scales of days to weeks. The variation of rates is usually expressed in units of number influx called the zenith hourly rate (ZHR; the rate of visible meteors seen by a standard observer under ideal conditions, that is, radiant in the zenith and the star limiting magnitude = 6.5):

$$\text{ZHR} = \text{ZHR}_{\text{max}} \times 10^{-|B(\lambda_0 - \lambda_{0,\text{max}})|} \quad [1]$$

This defines the duration parameter B (degrees⁻¹). λ_0 (J2000) is the solar longitude, a measure of time and related to the Earth's position in its orbit.

Meteor outbursts represent even larger flux variations, that are observed when Earth crosses a recently formed comet dust trail. In that case, rates can increase up to 5 orders of magnitude over a period of 1–2 hours. If the meteor rate increases to above 1 per second (or $\text{ZHR} > 1000 \text{ h}^{-1}$), the event is called a meteor storm. More important than such arbitrary nomenclature are the dynamical processes that underlie these manifestations. Comet dust trails are a manifestation of ejected dust grains returning at different times from their orbit around the Sun because of slightly different orbital periods. The encounter conditions with fresh comet dust trails vary from year to year because the position of the trails relative to Earth's orbit is a function of the combined influence of planetary perturbations, which move the trails in a pattern that mirrors the Sun's reflex motion around the barycenter of the solar system. Over time, the natural waving motion of the trails fades into a broader stream called the filament, which is due to small perturbations of the orbital period of grains so that different sections of a dust trail catch up on each other. The filament

causes meteor outbursts with a duration of about a day. Such structures persist only when the grains become trapped in mean-motion resonances that prevent close encounters with the planets, because such close encounters will put the grains in the annual shower component.

Meteor Luminosity

When a meteoroid encounters the Earth's atmosphere, an initial phase of V-shaped luminosity is seen, possibly caused by the interaction of released electrons with the ambient ionosphere. Leonids 1 kg in size have been detected as high as 196 km.

Most meteors are not seen until around 135–120 km, where massive evaporation of meteoric silicates starts to occur. The process is one of sputtering, where each impact of an air molecule releases a cloud of atoms and molecules from the meteoroid. That builds a small vapor cloud traveling along with the meteoroid. Subsequent air collisions are with the vapor cloud, creating a warm ($T \approx 4400 \text{ K}$) plasma in the immediate wake of the meteoroid.

When the pressure of the vapor cloud exceeds that of the ambient air, it expands as into a vacuum. The density falls off rapidly with increasing distance from the meteoroid, while the temperature increases. This region may be the source of an emitting gas ($T \approx 10\,000 \text{ K}$) detected in bright fast meteors. The size of the vapor cloud is a function of particle mass and speed, and about 1–10 orders of magnitude larger than the size of the meteoroid (Figure 3).

The wake of the meteoroid is formed by the impacting air molecules and by the vapor cloud products that receive any amount of momentum transfer, that is after a single collision. This is the main source of light emission at visible wavelengths and reflections. Head echoes are the signature of a hard (unresolved) target crossing the radar beam. The decelerated atoms will expand into the ambient air until stopped by subsequent collisions. The mean free path determines the initial radius (r_i) of the wake, which is of the order of a few meters and has the following expected dependence on velocity and atmospheric mass density (ρ_a):

$$r_i \approx \rho_a^{-1} V^{0.8} \quad [2]$$

Observed dependencies are less steep ($r_i \approx \rho_a^{0.4-0.8}$), perhaps due to fragmentation. At high elevations, the attenuation due to this dispersion leads to low electron densities and an 'echo height ceiling' effect in backscatter radar. For a radar at any given wavelength there is a height beyond which no underdense echoes can be seen.

'Overdense echoes' occur when the electron density remains high enough to cause mirror-like reflection. Sometimes, there are also 'head echo' reflections, which are the signature of a hard (unresolved) target crossing the radar beam: a spherical region of ionization that travels along with the meteoroid and may be related to the spherical region of optical luminosity in the bottom part of Figure 3.

The observed light intensity (I) and electron line density (q) are proportional to the rate of loss of kinetic energy from the ablated atoms:

$$I = 0.5\tau \frac{dm}{dt} V^2 \quad [3]$$

with τ the dimensionless luminous-efficiency factor $\tau \approx 0.01$, depending on the particulars of the meteor emission spectrum (changing with speed, size, etc.) and the instrument response.

The blue and green part of the optical spectrum consists mainly of ablated metal atom emission lines with a $T \approx 4400$ K, mostly from iron and magnesium lines. Fast and bright meteors show the violet Ca^+ doublet. The orange and red part of the spectrum are dominated by neutral oxygen and nitrogen lines and by the first positive bands of molecular nitrogen. Those atmospheric lines and bands are also well described by $T \approx 4000$ K vibrational temperature, electronic excitation temperature, and chemical equilibrium. Many deviations from local thermodynamic equilibrium are observed, however, and are the focus of study. Emissions from small organic molecules such as CN have been reported, but with insufficient certainty to derive quantitative information. The thermal infrared spectrum remains unexplored, while the near-UV spectrum is dominated by lines of Mg and Mg^+ at 280 and 285 nm (Figure 4).

For the typical response of the photographic plates used in the Harvard Super Schmidt program (m_{ph}), the brightness as a function of mass is given by

$$\lg M(g) = 5.15 - 0.44 * m_{\text{ph}} - 3.89 \lg_{10} V_{\text{inf}} (\text{km s}^{-1}) - 0.67 \lg_{10} [\sin(h_r)] \quad [4]$$

Figure 4 Optical spectrum of a Leonid meteor from data by Shinsuke Abe.

where h_r is the angle of incidence. The magnitude m_{ph} refers to an ‘absolute brightness’ at a distance of 100 km. On this scale, a zero-magnitude Leonid would weigh 0.07 g, and would emit visible light (400–700 nm) at a rate of about 500 W.

The relationship between visual meteor magnitude (m_v) and the number of electrons formed per meter of meteor path (the electron line density) is

$$m_v = 38 - 2.5 \lg_{10} q(\text{m}^{-1}) + 2.5 \lg V(\text{km s}^{-1}) \quad [5]$$

This density pertains to the wake shortly after it has formed. The density decays rapidly by ambipolar diffusion, with a coefficient $D \approx 4.2 \text{ m}^2 \text{ s}^{-1}$ at 93 km.

Altitude of Deposition

How is the ablated matter (and amount of ionization/chemistry) distributed as a function of altitude? The traditional approach is to assume the meteoroid mass loss to be proportional to the kinetic energy transferred to the intercepted air mass:

$$dm/dt = \frac{-\Lambda A}{2\zeta} \left(\frac{m}{\rho}\right)^{2/3} \rho_a V^3 \quad [6]$$

where ζ is the heat of ablation of the meteoroid material ($0.2\text{--}1.0 \times 10^3 \text{ Jg}^{-1}$); Λ is the dimensionless heat transfer coefficient that specifies the efficiency of the collision process in converting kinetic energy to heat (0.6, down to 0.1), A the effective surface area, and ρ the density of the meteoroid ($0.1\text{--}1.5 \text{ g cm}^{-3}$).

From this, the classical expression for the rise and fall of meteoric luminosity (or ionization) is derived. For given atmosphere density profile $\rho_a(H)$:

$$\frac{I}{I_{\text{max}}} = 9/4 * \frac{\rho_a}{\rho_a^{\text{max}}} * \left(1 - \frac{\rho_a}{3\rho_a^{\text{max}}}\right)^2 \quad [7]$$

where max denotes the altitude (H) of the peak brightness, which varies with entry velocity, zenith angle, and meteor brightness:

$$H_{\max}(\text{km}) = 21.2 + 44 \lg_{10} V(\text{km s}^{-1}) + 1.1M_{\max} \quad [8]$$

(and less for higher than typical meteoroid density).

Lightcurves from cometary meteoroids tend to be flatter than this and are better described by a sum of such classical lightcurves, the assumption being that a matrix material is evaporated or bonding sufficiently weakened for the meteoroid to break apart. Because there is not much momentum transfer to the grains, these fragments move along as a cloud of solid bodies. Because the larger fragments penetrate deeper than do the smaller ones, the size distribution determines the shape of the composite lightcurve. In the calculations, it is important to take into account the higher deceleration of the smaller fragments, with the resistance or drag equation:

$$\frac{dV}{dt} = -\left(\frac{\Gamma A}{m^{1/3} \rho^{2/3}}\right) \rho_a V^2 \quad [9]$$

with Γ ($= 0.5$ – 1.0) the drag coefficient. Evidence for such fragmentation comes from the early release of sodium relative to magnesium in optical spectroscopy, the detection of jets of debris fragments ejected by rapidly spinning meteoroids, and larger-than-expected emission volumes, among others.

The peak mass loss is also a function of the sublimation temperature of the mineral components of the meteoroid. Differential ablation is the term used to indicate the deposition of matter in successive order of volatility. The most volatile organic compounds with $T \approx 500$ K have their peak loss as high as 117 km in a fast 71 km s^{-1} Leonid, while the most refractory compounds with $T = 2400$ K are expected to have peak mass loss at 105 km altitude. For slower $T = 25 \text{ km s}^{-1}$ meteors, the organics are not lost until 90 km altitude in such models (Figure 5).

Evidence for differential ablation is much less abundant than expected. In general, optical emission spectra do not show evidence for differential ablation. Only in unusually fragile meteoroids do we see an earlier onset of the sodium than magnesium atoms, thought to be because the minerals involved are more efficiently exposed to the meteoric vapor plasma. Lidar observations of neutral atom debris trails, however, tend to

show only one of several metal atoms at a given altitude, which has been interpreted as evidence for differential ablation. Such trails are detected only minutes to hours after deposition, when they drift by the lidar beam (Figure 6).

Conditions in the Meteor Path after Deposition

Once the air is heated and meteoric matter has been deposited, the resulting pressure increase by more than a factor of 10 creates a shock wave which expands radially. Assuming that this expansion occurs adiabatically, then the pressure will equilibrate with the background atmosphere when the radius is about 70 m (example for a -12 -magnitude Leonid). Even at the very low pressures of the upper mesosphere/lower thermosphere ($<10^{-8}$ hPa), the size and velocity (Mach 270) of such a meteoroid would create a turbulent wake (Reynolds number >2000).

At this stage, the meteor is detected in several manners. First, a wake of the forbidden ‘green line’ emission at 557 nm from the O (1S – 1D) transition is seen in fast meteors, even relatively faint ones. The emission is thought to be produced by the Barth mechanism. Intensity estimates show that about 15% of the O_2 in the initial train is dissociated in a -12 magnitude Leonid.

Radar reflections have detected an extended wake out to 6 km and several seconds behind a meteoroid that contributes to nonspecular reflections at UHF and VHF frequencies. Plasma instabilities and turbulence are responsible for an anomalous cross-field diffusion of meteor trails in the Earth’s magnetic field that can be up to an order of magnitude faster than the rate expected from ambipolar diffusion. In bright fireballs, this wake is accompanied by an afterglow rich in metal atom line emissions, without the atmospheric emission lines that are typical for the meteor spectrum. The afterglow has been interpreted as due to secondary ablation from debris particles. Evidently, even a fast meteor can deposit solid debris in its path, if conditions

Figure 5 Beginning and end heights of Leonid meteors.

Figure 6 Lidar response to a neutral iron atom debris layer, measured by University of Illinois Fe boltzmann lidar.

are favorable. The ablation vapor cools from ~ 4400 K to ~ 1200 K in a few seconds. This afterglow is followed by a recombination emission phase that lasts tens of seconds. Mid-infrared emission remains detected for longer, even when the gas and dust has cooled to just 50 K over the ambient $T \approx 250$ K a few minutes after the fireball.

A persistent chemiluminescence remains for Leonids < -3 magnitude, which is called the persistent train (Figure 7). Those persistent trains can be visible at ~ 13 magn/arcsec² for many (tens of) minutes. The dynamical mechanism is not yet fully understood. Typically, two bright bands of light are seen with various levels of billowing. The train spectrum shows sodium emission lines and a broad molecular band continuum identified as the FeO orange arc band. The luminous mechanism is thought to be the catalytic recombination of ambient ozone with oxygen atoms in the trail through the Chapman airglow mechanism:

where the branching ratio of reaction [11] to produce the Na (3^2P) state (which then emits an orange photon at 589 nm) is about 10%. The FeO molecular emission band probably arises from

where reaction [12] is sufficiently exothermic to produce FeO in excited electronic states, leading to emission between 570 and 630 nm with about a 2% efficiency. Thus persistent trains serve as a model for natural airglow emission, in extreme conditions and with the reactive components separated. The trains also probe upper atmosphere winds, wind shear, and diffusion rates.

On the relatively short time scale of the train (minutes rather than hours), and particularly in the presence of elevated concentrations of atomic oxygen, it is very unlikely that the metallic species would be able to form more stable reservoir compounds such as NaHCO_3 or $\text{Fe}(\text{OH})_2$. Indeed, between 85 and 100 km the meteoric metals are overwhelmingly in the

atomic form in the background atmosphere. The postulated formation of nanometer-sized recondensed meteoric vapor particles in the warm meteor wake has not yet been demonstrated. However, when the metal atoms settle to lower elevations, they quickly react chemically and can condense to form particles. Most of this fine-grained material is expected to be transported to one of the poles, following seasonal winds in the upper mesosphere.

Impact of Meteors on the Atmosphere

Much remains unknown about the chemistry in the meteor wake plasma. Molecular abundances for equilibrium air plasmas show that the $T \approx 4400$ K temperature enables interesting organic chemistry in CO_2 -rich atmospheres, because not only CO_2 but also CO is dissociated. At slightly lower temperatures, much of the electron charge is balanced by NO^+ , while at higher temperatures much of the charge is carried by C^+ or O^+ . NO production rates may be affected by nonequilibrium processes and have not yet been calibrated by observations. The chemical changes of organic compounds in meteors are of particular interest, because meteors may have contributed more than two-thirds of all infalling organic matter on the early Earth, in a form determined uniquely by the chemistry in the meteor wake and subsequent terrestrial evolution.

Meteoric metals and ions contribute to a steady-state condition in the upper atmosphere. The influence of meteors may be measured directly during unusual disturbances of meteoric influx. Indeed, variations of OH airglow intensity with meteor shower rates have been reported in conjunction with the 1999 Leonid meteor shower. Tentative associations have also been made between meteor ionization and the occurrence of sprites and elves during lightning storms. Lightning has been observed to travel along the ionized path of a meteor. Much progress in these fields is expected in the near future.

Introduction

One frequently needs to analyze atmospheric observations or model outputs that are time-varying fields of data at many points in space. Typically, one desires to isolate a few important and physically interpretable modes of variability in the data. Until the 1960s, this was usually done subjectively, by constructing an index (such as the Southern Oscillation Index of sea-level pressure difference between Tahiti and Darwin) that appears to correlate strongly with the variability in one or more data fields (sea-level pressure, sea surface temperature, winds, precipitation) at many locations. Regressing this index onto the data or binning the data corresponding to different ranges of the index yields composite spatial patterns of variability.

To avoid the trial and error of concocting such indices, it has become common to use techniques that directly find dominant modes of variability in the data. This article describes some popular techniques for doing this.

We first discuss principal component analysis (PCA) and some variants. PCA seeks spatial patterns that explain the maximal variance in a single data field. We then examine popular methods for isolating important spatial patterns of coupled variability between several data fields. Such methods include maximum covariance analysis or MCA (also widely called singular value decomposition or SVD – we prefer the name MCA, suggested by von Storch and Zwiers in 1999, since SVD is the name of a fundamental matrix decomposition whose applications are far broader than this specific technique of spatial data analysis); canonical correlation analysis (CCA); redundancy analysis; and variations. We discuss space–time data fitting with a linear autoregressive model, called principal oscillation pattern (POP) analysis. All of the above methods are thoroughly discussed and referenced by von Storch and Zwiers (see [Further Reading](#)). Lastly, we briefly mention some nonlinear techniques for space–time analysis.

Principal Component Analysis

PCA was pioneered in the social/biological sciences by Hotelling and Pearson in the 1930s, and first applied to atmospheric data by Lorenz in 1956. Consider a multivariate data set $y_i(t_n)$ consisting of several samples (indexed by n) of a set of variables (indexed by i). In a biological science application, the variables might be the sizes of different body parts (forearm length, waistline, height, foot size, etc.), sampled across many people. In an atmospheric context, the variables might be annually-averaged sea-level pressure anomaly $y_i(t_n)$ at I observing stations $i = 1, \dots, I$, sampled for $N = 50$ years t_n , $n = 1, \dots, N$. PCA seeks a single linear combination of the variables that explains the maximal fraction of the overall sample variance.

Mathematical Derivation

This can be phrased as the following mathematical optimization problem. Let $y(t_n)$ be the vector of observations at time t_n . Any linear combination of these observations can be written $a(t_n) = \mathbf{u} \cdot \mathbf{y}(t_n)$, where $\mathbf{u}$ is a vector of station weights u_i . It suffices to take $\mathbf{u}$ to be a vector of unit norm. Then $a(t_n)$ is the projection of the data onto the direction $\mathbf{u}$, and $\overline{a^2(t)}$ is the explained variance (eqn [1]).

$$\overline{a^2(t)} = \mathbf{u}^T \overline{\mathbf{y} \mathbf{y}^T} \mathbf{u} = \mathbf{u}^T \mathbf{C}_{yy} \mathbf{u} \quad [1]$$

Here, an overbar represents an average over the N sampling times, and the (i, j) th element of the matrix $\mathbf{C}_{yy}$ is the covariance of y_i with y_j . In this language, PCA seeks a $\mathbf{u}$ that maximizes eqn [1] subject to $|\mathbf{u}| = 1$.

Since $\mathbf{C}_{yy}$ is a symmetric positive definite matrix, standard linear algebra tells us that the desired $\mathbf{u} = \mathbf{e}_1$, the eigenvector of $\mathbf{C}_{yy}$ corresponding to its largest eigenvalue λ_1 . If the other eigenvalues are ordered from largest to smallest, the k th eigenvector is the direction that explains the maximal variance

in the data and is orthogonal to all previous eigenvectors. This eigenvector is called the k th empirical orthogonal function (EOF) of y and the corresponding time series $a_k(t)$ of the projection of the data onto this EOF is called the k th principal component (PC). The data field can be exactly rewritten in 'canonical form' in terms of its EOFs and PCs (eqn [2]).

$$y(t_n) = \sum_{k=1}^I a_k(t_n) \mathbf{e}_k \quad [2]$$

Furthermore, the $a_k(t_n)$ are temporally uncorrelated, so the total variance in y summed over all spatial locations is just the sum of the eigenvalues λ_k , and the fraction of the variance explained by the k th PC/EOF pair is given by eqn [3].

$$f_k = \frac{\lambda_k}{\sum_{l=1}^I \lambda_l} \quad [3]$$

Owing to these orthogonality properties, the EOFs can be interpreted as spatial patterns of variability as well as just weight functions. In particular, if $y_i(t)$ is regressed on the k th PC, the regression slope is just e_{ik} , the i th element of the k th EOF. Thus $\lambda_k^{1/2} \mathbf{e}_k$ can be interpreted as the characteristic change of $y(t)$ corresponding to a one standard deviation ($\lambda_k^{1/2}$) change in the k th PC.

Practical Interpretation of PCA

In practice, only a few leading EOFs explain most of the variance of the field. Since most atmospheric fields have long-range spatial correlations, these EOFs typically correspond to patterns of broad spatial scale, and are relatively robust even when the number of samples is low or the data are noisy. Thus, the leading PCs are often useful index time-series for compositing with respect to the leading modes of variability of a given field. Often, 1–5 PCs explain as much as 90% of the overall variance in the field, and these PC/EOF pairs form an efficient low-dimensional description of the entire field. In this case, projection onto these PCs is a useful space/time filter before other statistical methods such as canonical correlation analysis are employed.

If the variability of the field is dominated by propagating disturbances (e.g., mid-latitude sea-level pressure variations on synoptic time scales), the corresponding eigenvalues come in a nearly equal pair corresponding to two phases of the disturbances that are in quadrature.

Because higher EOFs are forced to be orthogonal to their predecessors, they may not be amenable to simple physical interpretation. Furthermore, since the covariance matrix was estimated on the basis of a finite number of physical realizations, its EOFs may contain sampling biases. This problem becomes more acute for higher-index EOFs, and can also mix EOFs with closely spaced eigenvalues. North's criterion states that if the covariance matrix is constructed on the basis of N independent samples, its eigenvalues have sampling uncertainties $\delta\lambda_k \approx 2\lambda_k/N$, and if the spacing between successive eigenvalues is comparable to or less than this sampling uncertainty, their EOFs will be heavily contaminated by sampling uncertainty. Another simple check on the robustness of the PCA is to divide the data set into randomly chosen

halves, then examine the similarity of the EOFs given by the two halves.

Rotated PCA

The spatial patterns produced by PCA can sometimes be difficult to interpret. For instance, two ocean basins might have characteristic patterns of sea surface temperature anomalies that explain a lot of the intrabasin variability, but the variability in the two basins might only be weakly coupled. To maximize the leading mode variance and maintain an orthogonal second mode, PCA would yield a leading mode in which the spatial patterns in the two basins are in-phase and a second mode of slightly smaller explained variance in which they are out of phase. This might direct attention to the weak coupling between the basins rather than the much more robust intrabasin variability.

Rotated PCA (in statistical parlance, a type of factor analysis) can be used to obtain localized modes that might have a simpler physical interpretation. It consists of choosing a set of spatial weights or directions that optimize some measure of localization. The data are typically filtered onto the leading EOFs before this procedure is carried out. Varimax rotation, which is most commonly used, maximizes a function of the weights that tends to force them to be closer to either zero or one than regular PCA. This favors modes that are weighted mainly to a few spatial points, inhibiting mode mixing of the kind discussed above. However, the modes are no longer temporally uncorrelated (hence they do not form a partitioning of the variance) and may not be spatially orthogonal for some rotation strategies. Furthermore, the leading mode will not explain so much of the variance as with regular PCA, and many spatial patterns do not have the localized character that rotated PCA selects for, so this method should be applied thoughtfully.

PCA for Propagating Disturbances

Several methods for extending PCA to better analyze spatially propagating disturbances have been proposed. One such technique is complex PCA (CPCA), in which a discrete Hilbert transform in time is applied to the field of data. A new field is created whose real and imaginary parts are the original field and its Hilbert transform. A PCA of the (now complex) covariance matrix of this field yields complex eigenvectors whose real and imaginary parts give the characteristic spatial patterns in both phases of the wave.

Singular Spectral Analysis (SSA)

Many modes of spatial variability have characteristic time evolutions, for instance, the life cycle of a baroclinic cycle. Singular spectral analysis is a method popular in some circles for characterizing the dominant patterns of space–time variability, and has been used as an alternative to power spectral analysis. Conventional PCA is based on the matrix of simultaneous (unlagged) covariances. SSA is based on PCA of an extended covariance matrix that also includes lagged covariances with a sequence of time lags. The EOFs are parsed into characteristic spatial patterns evolving through the sequence of lag times.

Methods for Isolating Patterns of Coupled Variability

Two linear methods, MCA and CCA, are widely used for isolating patterns of coupled variability in two fields. A third method, called 'redundancy analysis' (RA) by von Storch and Zwiers, is also useful for predicting the time-space structure of one field based on observations of another, correlated field.

Mathematically, these methods can be phrased as follows. We call the two fields the 'left' field $y_i(t_n)$ and the 'right' field $z_j(t_n)$. For example, we might look for coupling between monthly anomalies of tropical Pacific sea surface temperature at an array of buoys (left field) with monthly gridded Northern Hemisphere 500 hPa height anomalies (right field). The two fields must be given at the same time, but not necessarily at the same spatial locations.

Maximum Covariance Analysis (MCA)

MCA (also commonly known as SVD) was first applied to an atmospheric problem in 1976 by Prohaska, and was comprehensively compared with other methods of space-time analysis by Bretherton and colleagues. MCA finds an optimally coupled left spatial pattern $\mathbf{u}$ and a right spatial pattern $\mathbf{v}$, both unit vectors. They are chosen such that the projection $a_1(t) = \mathbf{u} \cdot \mathbf{y}(t)$ of the left-field values onto the $\mathbf{u}$ direction has maximal possible covariance with the corresponding projection $b_1(t) = \mathbf{v} \cdot \mathbf{z}(t)$ of the right-field values in the $\mathbf{v}$ direction. The solution is obtained by singular-value decomposition of the cross-covariance matrix C_{yz} between the gridpoint values of the left field and those of the right field. If its left and right singular vectors are $\mathbf{l}_k$ and $\mathbf{r}_k$, ordered from largest to smallest singular value σ_k , then the optimal $\mathbf{u}$ and $\mathbf{v}$ are the leading left and right singular vectors $\mathbf{l}_1$ and $\mathbf{r}_1$. Succeeding singular vectors define coupled spatial modes that maximize the covariance subject to orthogonality with the previous modes. Unlike with PCA, the corresponding modal amplitudes may be temporally correlated.

MCA is efficient to numerically implement, requires no prefiltering of the fields, and produces spatial patterns that exhibit broad coupling over as much as possible of the spatial domains being analyzed. Its optimality characteristics usually provide excellent results, but there are caveats. One is that even if two fields are perfectly linearly coupled (e.g. a two-dimensional streamfunction and corresponding vorticity field), MCA may only approximately identify this coupling. A second caveat is that as with PCA, the spatial orthogonality constraints on succeeding spatial patterns may mix physically distinct but spatially nonorthogonal modes of variability.

Canonical Correlation Analysis

CCA, first developed by Hotelling in 1936, seeks a linear combination $a(t) = \mathbf{u} \cdot \mathbf{y}(t)$ of the left-field values and a linear combination $b(t) = \mathbf{v} \cdot \mathbf{z}(t)$ of the right-field values that have maximal temporal correlation. This optimality criterion is similar to MCA (which maximizes covariance). In practice, the difference is that CCA can choose linear combinations that explain little of the variance in their field

but are highly correlated with the other field. MCA will select linear combinations that explain significant variance in their fields but may be slightly less well correlated with the other field.

The optimal solution can be found by first performing PCA on each field. This yields standardized left and right principal components $\alpha_k(t)$ and $\beta_l(t)$. Then a singular value decomposition is performed on the cross-covariance matrix between $\alpha_k(t)$ and $\beta_l(t)$. The left/right singular vectors are transformed back into gridpoint coordinates to get the weight vectors $\mathbf{u}_k/\mathbf{v}_k$. The singular values are the correlations between the corresponding time-series $a(t)$ and $b(t)$.

To obtain robust results with CCA if a limited number of times have been sampled, one should first prefilter the data onto a small set of leading principal components of each field (that collectively explain 70–90% of the variance) to avoid spurious large correlations associated with overfitting. In this case, CCA tends to give quite similar results to MCA for the leading pattern. Successive patterns are temporally uncorrelated but may be spatially nonorthogonal. CCA is slightly more numerically intensive than MCA, and the prefiltering step slightly complicates the analysis procedure. However, it can sometimes be preferable if strong coupling between the fields is geographically localized.

Redundancy Analysis

In redundancy analysis, an application of multiple regression first developed in the 1970s, one tries to explain the maximal fraction of the variance of the right (predictand) field using the left (predictor) field. This can be viewed as a collection of least-squares multiple-regression problems for the right-field values at each location. As with CCA, prefiltering is recommended to avoid overfitting of the data.

Aggregated PCA

The above methods look for coupling between two scalar fields. Coupling between more than two fields, or a vector field and a scalar field, can be handled by aggregating some of the fields after standardizing them to comparable variance, and analyzing coupling between two aggregated fields. Another approach in this case is to aggregate all of the fields into a single field, whose modes of variability are found using PCA. The resulting modes optimize a combination of the explained variance within individual fields and the covariance between fields, and may not pick out the patterns of coupling between the fields as effectively as the previous methods.

Principal Oscillation Pattern (POP) Analysis

Some physical systems can profitably be idealized as a damped linear response to stochastic forcing. POP analysis fits such a model to the space-time variability of a field or coupled fields. Given a vector $\mathbf{y}_n$ of observations at times t_n of one or more fields at one or more locations, the fitting model has the form of eqn [4].

$$\mathbf{y}_{n+1} = \mathbf{A}\mathbf{y}_n + \mathbf{f}_n \quad [4]$$

The stochastic forcing $\mathbf{f}_n$ is a noise vector uncorrelated between observation times, and $\mathbf{A}$ describes the evolution of the unforced system. The eigenvalues of $\mathbf{A}$ should all have magnitudes less than one, so that this model can describe a statistically stationary process. The corresponding eigenvectors of $\mathbf{A}$ (the POPs) describe the characteristic unforced patterns of spatial variability of the system; those with eigenvalues near to one in magnitude are slowly damped and will tend to dominate the observed response. Complex eigenvalues correspond to damped oscillations; the corresponding POPs are also complex, and the real and imaginary parts of the POP describe the oscillations in the spatial structure of the response.

To estimate $\mathbf{A}$ from the data, consider the expected value $E[\cdot]$ of an outer product of eqn [4] with $\mathbf{y}_n$ (eqn [5]).

$$E[\mathbf{y}_n \mathbf{y}_{n+1}^T] = \mathbf{A} E[\mathbf{y}_n \mathbf{y}_n^T] \quad [5]$$

From eqn [5], $\mathbf{A}$ can be estimated based on the empirical lag-0 and lag-1 covariance matrices.

Nonlinear Methods

The above 'linear' analysis techniques decompose an observed field into the sum of modes, each of which is the product of a spatial pattern and a time-varying amplitude. Some

phenomena, such as ENSO sea surface temperature variability, show a somewhat different spatial anomaly pattern in the positive phase from that in the negative phase, and may be more efficiently described as nonlinear modes whose pattern covaries with their amplitude. One standard check for this behavior is to composite the spatial anomalies corresponding to positive and negative values of an index time-series and see whether they are substantially different in structure. Neural net techniques have recently been developed that may prove to be useful for isolating such nonlinear modes of variability.

Data Analysis: Time Series Analysis

Synopsis

A sequence of data entries is called a time series. Most time series have a random character. A time series where there is no correlation from one member of the series to another is called *white noise*. Models of time series can be constructed from white noise by having each new entry a sum of a white noise contribution and a linear combination of previous entries. Special insights can be gained by examining the Fourier representation of the time series by developing it into a series of sinusoids of different frequency. A brief review of the technique is presented with attention to errors due to the limited sample or record length of a given time series.

Introduction

The study of the records of weather and climate over time is extremely valuable for practical as well as theoretical purposes. For example, the instantaneous temperature or humidity taken at hourly intervals constitutes a time series of measurements. Long records of data might be used for many purposes such as assembling a climatological summary for the site or for performing an analysis to identify the underlying physical processes responsible for certain interesting features of the data. In such an example, one might not be surprised to find a daily swing of the temperature and humidity as well as an annual oscillation. Were we to plot these hourly temperatures, a nearly repeating graph of period 24 h would result (the diurnal cycle). Examination over longer time spans leads to the identification of an annual cycle in the data. By simple inspection, one would rather quickly decide that there is some underlying physical agent responsible for these near repetitions or periodic statistics in the data stream. This is an example of the most primitive form of time series analysis.

Many decades of experience have led environmental and statistical scientists to devise very sophisticated methods of studying records of time series. The most powerful innovation is the idea of a mathematical model of the time series. A mathematical model involving random components is a very convenient way of representing a time series of data. Such models always employ simplifying assumptions, but such techniques work in a surprisingly large number of applications, especially in the geosciences. The idea of a random variable must be introduced before describing how such a time series can be constructed. A random variable can take on values drawn from a certain probability distribution. For example, the outcomes of flipping a coin are a random variable. Each flip constitutes a realization of the random variable – either heads (H) or tails (T). The probability distribution is 50–50 (probability 0.5 for H, 0.5 for T). More commonly encountered in geophysical and behavioral sciences is the case where the variable can take on a range of discrete or continuous values and its frequency distribution is the normal or bell-shaped curve distribution. An example is the distribution of heights of individuals. Drawing names from a hat and announcing the height of the individuals is equivalent to generating realizations of the height random variable. Most realizations of such a process yield values near the center of the bell-shaped curve, with large excursions from the

population average being very rare. The mean of a random variable is the arithmetic average of its values taken over many realizations (actually the limiting value derived from infinitely many). The variance is the average of the squares of the deviations from the mean. The deviation from the mean for two variables can be multiplied together and averaged over many realizations to form the covariance of the two random variables. As the name implies, the covariance is a measure of how two random variables covary. If the two variables are identical then their covariance is simply the variance. If the two variables are not statistically related to one another then the covariance is zero. The correlation between two random variables is the covariance divided by the square root of the product of the variances. Its magnitude is always less than or equal to unity. Anticorrelated variables have negative correlation (and covariance). In a time series, one is often interested in how an entry covaries with or is related to past (or future) entries. In particular, one would like to know if it is correlated with immediately past entries, a property known as serial correlation.

White Noise

The simplest model of a randomly based time series is one in which each new time step leads to a statistically independent (no serial correlation) drawing (like the heights of individuals above); but each new entry Z_n is drawn from an identical distribution. Each data entry is statistically independent of the previous ones. This model is called the statistically independent, identically distributed *white noise* model. It is the most important model in time series analysis since almost all other statistical models are derived from it. A few properties of the white noise model (it is hereafter assumed that the identically distributed property is included) are worth mentioning. First, the mean of the entries of such a time series can be estimated by adding the values of a long series of entries and dividing by the number of entries used. In doing this, an estimate of the underlying mean of the probability distribution of the individual entries is found. Another property of time series that is easily demonstrated with the white noise model time series is that an independent realization of a time series. Above the random variable was introduced. In time series, there is a random function or string of random variables, with individual realizations being individual graphs of the function. The property that is so evident is that

Figure 1 A white noise process with normally distributed entries having mean zero and standard deviation unity. The time series has length $N = 500$.

averaging along the time series is equivalent to fixing the time and averaging across realizations to find the mean. This property of *ensemble averaging* is a very powerful one, which enables many of the proofs and analyses of time series analysis. An example of a single realization of a white noise process is shown in [Figure 1](#). An example of a white noise time series is the heights of students standing in a cafeteria queue. On the other hand, consider the heights of succeeding first sons in an ancestral sequence. There is a genetically determined correlation between the height of a father and that of his son. Such a time series exhibits a positive serial correlation which diminishes to zero after a few generations, a phenomenon known as regression to the mean.

Stationary Time Series

Consider next a time series that is not necessarily white noise. That is to say, an entry may not necessarily be statistically independent of its predecessor – there may be serial correlation. Nevertheless, the time series may not have any preferred origin. That is, as seen along the time series, statistically speaking, each time is equivalent to each other time. In such a time series, the mean is independent of time and so is the variance. The covariance between an entry and that a certain number of steps, say n , earlier depends only on the temporal separation or lag, m . A time series having the above properties is called a stationary time series and these are common in nature. (Strictly speaking, this only defines a second moment stationary time series, since nonstationary properties of the probability distribution may still be present. If the random variables are normally distributed, these mean and covariance stationary properties suffice to determine the strong forms of stationarity.) Perhaps some examples of nonstationary time series will help clarify the concept. The diurnal or seasonal data mentioned above are examples of nonstationary time series since their means depend on local time of day or time of year. In addition, their variances might also have such a phase dependence; even their serial correlation structure may have a phase dependence for example, the serial correlation between entries may be greater in winter than in summer. At first glance, the sequence of heights of first sons across generations may

seem like a stationary time series, but there is known to be a secular trend of increasing heights over generations, probably because of better nutrition.

Despite the ability to enumerate many time series in nature that are nonstationary, the model of a stationary time series is very valuable in the geosciences. For example, annual averages of temperature at a location are likely to form a stationary time series at least to a good approximation. In some cases, the nonstationarity can be eliminated by removal of a trend in the mean or by some other simple modification. The statistics of such time series (mean, variance, serial correlation properties) make a good summary of the sequence and for many purposes may form an adequate substitute in practical applications. For example, an insurance company may want to know the likelihood of the temperature (or flood water level) exceeding a given threshold. The serial correlation structure is particularly important in drought, where sequences of dry years can be the most important indicator of consequences.

Autoregressive Processes

The most common type of time series encountered in the geosciences is the first-order autoregressive process (known as the AR1 process). In this process, each new entry can be written mathematically as the sum of two terms, the first proportional to the previous entry and the second an additive white noise term.

$$T_{n+1} = \lambda T_n + Z_n \quad [1]$$

where T_n is the random variable at time step n and Z_n is a white noise disturbance ordinarily taken to be normally distributed with mean zero and variance unity. λ is a parameter ($|\lambda| \leq 1$) that determines the lagged autocorrelation function, which can be shown to be given by λ^m , where m is the lag. Values of λ close to unity lead to long autocorrelation times, and small λ yields short autocorrelation times. Higher order autoregressive processes (ARp) model the next entry as a sum of $p + 1$ weighted terms. The weights are parameters similar to λ above. The final term is the additive white noise Z_n . Here it is concentrated on the AR1 process because of its central importance especially in geophysical applications. The parameters that describe the time series are its mean, its variance, and its so-called lag-one serial correlation. It is the job of the analyst to take the given data series and determine the parameter values that come closest to fitting the data. That is, one wants to know the mean, variance, and lag-one serial correlation in the data. If the lag-one serial correlation turns out to vanish, then one infers that the series can be modeled by a white noise time series (AR0). For the AR1 process, if the lag-one serial correlation is λ then the lag-two is λ^2 , and so on. In the limit of very small time steps in the series, this tends to an exponential falloff of serial correlation. The value of n for which the serial correlation falls to $1/e$ (e is the base of natural logarithms = 2.718 ...) is known as the autocorrelation time. The autocorrelation time is a measure of the memory of the system. It is often said that the system forgets its past values after a few autocorrelation times ([Figures 2 and 3](#)). The heavy line in [Figure 3](#) shows the ideal autocorrelation function λ^n for the process, while the thin lines indicate sample estimates based on a time series of length 500. The spread of these estimates suggests

Figure 2 Realization of an AR1 time series with $\lambda = 0.8$. The time series has length $N = 500$. The discrete points (spaced 1 time unit apart along the time axis) along the curve have been connected with straight lines.

Figure 3 The lagged correlation function for the AR1 process with $\lambda = 0.8$. The discrete points (spaced one lag unit apart along the horizontal axis) along the curves have been connected with straight lines. The heavy line represents the ideal autocorrelation for $N \rightarrow \infty$, while the thin lines are sample estimates from five realizations of length $N = 500$.

size of the error involved in using a sample even as low as $N = 500$, especially when the value of λ is close to unity.

Fourier Analysis of Time Series

If there are physical reasons to think that a time series of data is stationary, then Fourier analysis of the data can lead to a number of powerful techniques useful in applications. One begins the analysis by taking the finite-length segment of data in the sequence and estimating the Fourier coefficients for representing the data as a Fourier series on the segment.

In this process, one is representing the data in terms of the Fourier coefficients instead of the temporal entries. The two are equivalent ways of expressing the content of the data. The discrete Fourier transform and its inverse are given by:

$$\tilde{T}(f_s) = \sum_{n=0}^{N-1} T_n e^{2\pi i f_s n} \quad \text{and} \quad T_n = \frac{1}{N} \sum_{s=0}^{N-1} \tilde{T}(f_s) e^{-2\pi i f_s n} \quad [2]$$

where $f_s = s/N$; $s = 0, 1, 2, \dots, N-1$; and N is the length of the sample time series. $\tilde{T}(f_s)$ is a component or (complex)

amplitude of a certain sinusoidal waveform in the data stream. From the point of view of time series modeling, the Fourier coefficients $\tilde{T}(f_s)$ are random variables, since from one realization of the process on the same time span to another realization the coefficients will differ. However, they will have certain statistical properties common across the ensemble of realizations. If the segment is sufficiently long and the series is stationary, it can be shown that the Fourier coefficients corresponding to different frequencies are uncorrelated – a very powerful statement. This permits us to perform an analysis of variance over the different frequency bands to examine how variance is distributed (additively) over frequencies. It is routine to plot a graph of the variance or sometimes known as power as a function of frequency. This is known as *spectral analysis*.

The most common example is the white noise time series. The white noise spectrum is flat; that is, every equal width frequency band has allotted to it the same variance. Hence, one way of determining whether a certain time series is white noise is to perform the Fourier analysis and plot the spectrum (variance or power versus frequency). The *periodogram* is the most elementary but direct characterization of the sample spectrum.

$$S^{(p)}(f_s) = \frac{1}{N} \left| \sum_{n=1}^N T_n e^{2\pi i f_s n} \right|^2 \quad [3]$$

An ensemble average across many equal length temporal segments of the same process leads to the *spectral density* if f_s is taken to be a continuous variable (smoothing across the discrete values f_s). If the spectrum is flat, one can infer that the time series is white noise. Of course, if the time series segment is short, there will be problems in estimating the spectrum of the underlying process because of sampling error. This is illustrated in **Figure 4** for a white noise sample of length 500.

The periodogram shown in **Figure 4** is anything but flat. It represents the magnitude squared of each of the discrete Fourier coefficients. Since each periodogram component is half the sum of the squares of the sine and cosine coefficients (each of which is normally distributed), the random variable representing each Fourier component of the periodogram can be shown

Figure 4 Periodogram for a white noise process with $N = 500$. The mean of this periodogram entries is 1.001 79, and the variance is 0.891 73; theoretically they should approach unity as N increases. Note that the periodogram is an even function about $s = 250$ or $f_s = 0.5$.

to obey an exponential distribution with mean and variance unity (actually this is one half the sum of two $\chi^2_{[1]}$ variables). Adding more terms to the time series (increasing N) does not reduce the error for an individual Fourier element in the periodogram. If one averages across many frequencies, one can smooth the periodogram and reduce the error variance of the spikes. The averaging works because the separate frequency variance components are statistically independent and this means that averaging over more lines smooths out the error proportionally to $1/\sqrt{w}$, where w is the width of the frequency band. This is one way to reduce the error for a band. The tradeoff is that by reducing error by widening a band, you give up spectral (frequency) resolution. The approach using the periodogram to estimate spectral density has many faults including bias (error in estimating the mean of a quantity even as $N \rightarrow \infty$) along with random sampling error. **Figure 5** shows the log of the ideal spectral density for $N \rightarrow \infty$ as the heavy black line. The colored thin lines are periodogram estimates based on four realizations of the AR1 process with $\lambda = 0.8$ and for $N = 500$. The variance about the heavy black line is large with many spurious peaks due to sampling error. In addition, there is a noticeable high bias that appears to be independent of frequency.

Errors are inevitably introduced because the sample has finite length, and attempts are being made to estimate the spectral density of an ideal infinite length time series from which the sample record was drawn. A raw finite length sample as in the time series shown in **Figure 1** begins abruptly at $n = 1$ and ends suddenly at $n = N$. This is equivalent to taking a segment of the infinitely long time series and multiplying it by a hard-edged rectangular function. Fourier transforms do not like sharp edges and they tend to introduce biases in the transformed variable. By way of a far too brief explanation, note that the absolute magnitude squared of the Fourier transform of a rectangular function symmetric about the origin has a central hump in frequency but with wiggly lobes on either side. The side lobes mix variance that should appear at one frequency band into frequency ranges nearby – peaks can turn into

multiple peaks or they can get displaced or smeared, etc. One way to mitigate this weird behavior is to apply a smooth taper on the time series segment at each end, but this is still unsatisfactory, although it is a step in the right direction. Some more satisfactory methods will be briefly discussed in the next section.

Introduction to Advanced Methods

The lagged covariance was introduced earlier. For a stationary time series T_n , it is given by

$$\tilde{\gamma}_m = \frac{1}{N-m} \sum_{n=1}^{N-m} T_n T_{n+m} \quad [4]$$

where $\tilde{\cdot}$ is used to indicate that the lagged covariance is a sample estimate. It is not difficult to show that eqn [3] is equivalent to

$$\tilde{S}(f_s) = \sum_{m=-M}^M \gamma_{|m|} e^{2\pi i f_s m} \quad [5]$$

where $M = \frac{1}{2}(N-1)$; N needs to be odd. If there is a periodic component of T_n , its lagged correlation will peak at lags equal to integral multiples of the periodic signal. The way to smooth the effects of the abrupt beginning and ending is to introduce a so-called lag window w_n into eqn [6].

$$\tilde{S}(f_s) = \sum_{m=-M}^M \gamma_{|m|} w_{|m|} e^{2\pi i f_s m} \quad [6]$$

The lag window $w_{|m|}$ can be a positive valued hump-shaped function (whose sum adds to unity) peaked $m = 0$. The hump needs to be wide enough to include roughly 10 oscillations of any important periodic signals that are being sought out in the spectrum. This gives us an idea of how long a time series segment needs to be in order to distinguish low-frequency phenomena. Numerous lag window shapes have been studied

Figure 5 Heavy black line: the ideal log–log spectral density versus frequency for the AR1 process ($\lambda = 0.8$) shown in **Figure 4**. The values of the ordinate are connected with straight lines. The time series has length $N = 500$. Frequency is in units of $1/250$ cycle per unit time. The sampling rate is 1 per unit time for this process. The thin colored lines are periodograms for four separate realizations of the time series.

including a tent shape (Bartlett window) and various smoother ones including the Parzen window. They have the property of introducing an equivalent bandwidth to the spectral estimate similar to smoothing the periodogram, but both approaches are subject to biases. Figure 6 shows log of spectral density estimated with the Parzen window ($m = 200$) for the ideal spectrum (heavy black line, same as in Figure 5) with four realizations of the same time series, of length $N = 500$. While the Parzen window technique reduces the variance about the true spectral density, it shows a definite high bias at high frequencies.

The most favored methods are the multitaper techniques. Studies suggest that the bias at higher frequencies is somewhat reduced by the multitapering method. This approach introduces a series of data tapering functions. These functions are mutually orthogonal and have certain other optimal properties, related to maximizing the variance in a given spectral band for a given length of the time series segment available. The procedure is to obtain the spectral estimate from each of the tapered time series records, then estimate the spectrum from each, followed by taking a weighted average of the spectral estimates. The tapering functions turn out to be the discrete prolate spheroidal wave functions. This technique is discussed in the book by Percival and Walden (1993).

Applications of Time Series Analysis

Not only do time series analyses provide new insights into the underlying physical processes generating an empirical time series, but they are useful in a variety of practical applications.

A very common use of time series analysis is data smoothing. Often one wishes to smooth out the highly irregular short-term fluctuations in a time series to get a better view of longer term trends or undulations. This can be accomplished by running a smoother over the time series. For example, one might take as the value at a certain time the arithmetic average

over several future and past values. These past and future entries can be weighted in various ways to make the smoothing optimal for the particular application. This class of operations is known as moving average smoothing. Perhaps, the most important application is forecasting.

One might ask, given a segment of a data-derived time series, is it possible to use this information to forecast future entries. The answer in principle is simple. In the case of a white noise time series (or an empirical one which is indistinguishable from white noise), there can be no forecast skill, since the next entry is statistically independent of the past entries. But in the case of an AR1 process, there is correlation with past entries and this will permit some statistical estimate of future entries out to roughly one or two autocorrelation times. The estimate will not only provide a most probable value of the future entry, but some assessment of the uncertainty in the forecast perhaps even a theoretical frequency distribution of values that can be expected. Interpolation is a second application of time series modeling. Suppose there are missing values in an empirical time series and for some reason one wishes to insert values that are statistically consistent with the rest of the entries. First, one finds a model of the time series and then one can find the most probable entry with an associated theoretical frequency distribution. Depending on the application, one may wish to insert the most probable value or add to it a random number which is consistent in a statistical sense with the nearest neighbors. A third application is in the area of signal processing. One often finds a deterministic signal embedded in some kind of noise (white or colored). The object usually is to separate the noise from the signal and to estimate the amplitude of the signal. This is the problem in radio reception. The process is referred as detection. By time series modeling and knowing some characteristics of the signal waveform, one can find an optimal estimate of the signal strength. In electronics, one might want to clean the noise away from the signal and amplify the residual, while in other applications, one might want to find the amplitude of a periodic signal such as the diurnal or

Figure 6 Heavy black line: the ideal log spectral density versus frequency for the AR1 process ($\lambda = 0.8$) shown in Figure 5. The values of the ordinate are connected with straight lines. The time series has length $N = 500$. Frequency is in units of 1/250 cycle per unit time, and the horizontal axis only extends to 80 of 250 cycles per unit time increment. The sampling rate is 1 per unit time for this process. The thin colored lines are periodograms for four separate realizations of the time series.

seasonal cycle. One of the most famous applications of this type in the geosciences is the detection of periodic signals in the record of changes in continental ice sheet volume. These excursions have been found to contain significant variance peaked at periods of 100 000, 43 000, and 20 000 years, and these just happen to coincide with the periods of the changes in the elliptical orbital parameters of planet Earth (eccentricity, obliquity, and precession of the equinoxes). Thus, time series analysis was able to show conclusively that the ice ages are linked to the changes in the Earth's orbital elements.

Synopsis

Ozone is a key stratospheric constituent. Its basic variations with latitude, height, and season are presented. The main chemical cycles are introduced. These are the Chapman (oxygen-only) reactions and a variety of catalytic cycles, driven by radical species whose stratospheric concentrations are orders of magnitude lower than that of ozone.

Introduction and Background

Ozone is perhaps the most important stratospheric constituent. It absorbs solar ultraviolet radiation, particularly strongly at wavelengths below about 310 nm, where stratospheric ozone acts as a filter to protect life at the surface from these potentially harmful wavelengths. Absorption of solar radiation by ozone also results in heating of the stratosphere and leads to the observed stable temperature structure, where temperature increases with height throughout the stratosphere. Ozone is also infrared active and is an important gas for the climate system. For these reasons, the chemistry of the stratosphere is essentially the chemistry of ozone and the minor constituents involved in ozone chemistry.

In the troposphere, ozone is present in mixing ratios (the ratio of the concentration of ozone to that of air) of a few tens of parts per billion by volume (approximately $\text{few} \times 10^{-9}$, or a few ppbv) but its peak mixing ratio is much greater in the stratosphere, reaching almost 10 ppm (10×10^{-6} , or 10 ppmv) at just above 30 km (10 hPa) in low latitudes. **Figure 1** shows seasonally averaged mixing ratios of ozone in the stratosphere and mesosphere based on satellite and ozone sonde data. In contrast, the largest absolute concentrations of ozone are found

in high latitudes between 20 and 25 km and reach a few times 10^{12} molecules cm^{-3} . Another useful measure for ozone is its column abundance, the vertically integrated density of ozone above the surface (also often called 'total ozone'). For most species column densities are measured in molecules per square centimeter. For ozone, the traditional unit is the Dobson unit (DU), named after the Oxford scientist, who pioneered the routine measurement of column densities using spectrophotometers to measure the absorption by atmospheric ozone of the solar spectrum in the 1920s. A DU is a thickness of 1 millimeter at standard temperature and pressure. Typical column densities are 250 DU in the tropics, with little seasonal variation, and 400 DU in high latitudes in winter and spring. **Figure 2** shows the average variation of the ozone column, as a function of latitude and month, obtained from satellite measurements by the total ozone mapping spectrometer (TOMS) satellite instrument.

As we will see below, the ozone distribution is in part controlled by radical species, which themselves are present in even lower concentrations. Typical mixing ratios of the oxides of nitrogen are in the part per billion range, while for active chlorine species peak values are usually around or below a part per billion. Mixing ratios of odd-hydrogen species are even lower. The radicals themselves are produced from source gases,

Figure 1 Seasonally averaged zonal mean cross section of ozone mixing ratio (ppmv) constructed from a combination of satellite and ozone sonde data by the Free University of Berlin. Courtesy of Dr Ulrike Langematz (FUB).

Figure 2 Long-term average latitude–time variation of the monthly and zonally averaged ozone column density (Dobson units) based on the available TOMS satellite data from November 1978 to December 1999. The values are repeated for 2 years to emphasize the annual cycle. The instrument measures reflected solar radiation, and the data gaps are in regions of darkness or twilight. Figure produced by Dr Peter Braesicke (University of Cambridge) from the original TOMS data (<http://toms.gsfc.nasa.gov/ozone/ozone.html>).

of both natural and anthropogenic origin and emitted in the troposphere. Thus, nitrous oxide is emitted from the Earth's surface and is relatively inert, and hence well mixed, in the troposphere with a present concentration of about 310 ppbv. It is oxidized in the stratosphere to produce NO (and hence NO₂). Similarly, water vapor (2–6 ppmv in the stratosphere) and methane (about 1.5 ppmv at the tropical tropopause) are

oxidized to yield the odd-hydrogen species H, OH, and HO₂. The halogen species, which have played an important role in ozone depletion during the last two decades, are mainly of recent anthropogenic origin. Their major source gases include CH₃Cl (with predominantly natural sources), CF₂Cl₂, and CFC₃. These latter species are the so-called freons, which were widely used in aerosol spray cans, refrigeration, and foam

blowing and are now regulated under the Montreal Protocol. Along with a number of other chlorinated species, these led to the present-day abundance of chlorine in the stratosphere of about 3.5 ppbv. Similarly, there is about 20 ppt of bromine in the stratosphere, arising from the degradation of methyl bromide (which has both natural and anthropogenic sources) and other industrially produced bromocarbons, used, for example, as fire retardants.

Odd Oxygen and the Chapman Reactions

In 1930, Sidney Chapman proposed a series of reactions to explain the distribution of stratospheric ozone of which the most important are:

(M represents any third body, usually N_2 or O_2 , required to conserve energy and momentum in a termolecular reaction).

Note that, in the troposphere and stratosphere, the photolysis of oxygen is much slower than the photolysis of ozone. Reactions [2] and [3] are rapid and have very short time constants for the conversion of O to O_3 and vice versa, and they establish a steady state much more rapidly than reactions [1] and [4].

$$J_3[\text{O}_3] = k_2[\text{O}][\text{O}_2][\text{M}] \quad [5]$$

([] represents concentration).

Note also that reactions [2] and [3] only interconvert the 'odd-oxygen' species O and O_3 ; i.e., they conserve odd oxygen ($[\text{O}] + [\text{O}_3]$). In contrast, odd oxygen is formed by reaction [1] and removed by reaction [4].

Thus, we can write for the rate of change of odd oxygen

$$d([\text{O}] + [\text{O}_3])/dt = 2J_1[\text{O}_2] - 2k_4[\text{O}][\text{O}_3] \quad [6]$$

The time scale for steady state between reactions [1] and [4] varies strongly with altitude, being on the order of hours at 40 km but on the order of many years at 20 km. Invoking steady state in the upper stratosphere (i.e., setting $d([\text{O}] + [\text{O}_3])/dt = 0$) is thus a good approximation. In the low stratosphere, it would clearly be a poor approximation since many external factors (the intensity of solar radiation, temperature, atmospheric transport, etc.) will all vary much more rapidly.

In the upper stratosphere, setting $d([\text{O}] + [\text{O}_3])/dt = 0$, we can calculate the steady-state distribution of ozone from eqns [5] and [6]:

$$[\text{O}_3] = (k_2J_1[\text{O}_2]^2[\text{M}]/k_4J_3)^{1/2} \quad [7]$$

Equation [7] describes the steady-state ozone concentration in an oxygen-only atmosphere. The vertical profile derived from eqn [7] is consistent with the shape (but not the

magnitude) of the observed profile, especially in low latitudes. Thus, eqn [7] predicts a peak in the ozone mixing ratio at a little above 30 km. However, this equation also predicts that the ozone concentration should be very low in high latitudes, when, for example, the photolysis rate of molecular oxygen, J_1 , becomes very low. However, observations show large column amounts of ozone in high latitudes in winter and spring (see Figure 2), when photolysis will be at its slowest. The reason for the discrepancy lies in the long photochemical time constant for ozone at low altitudes. When the time constant is long, the transport of ozone must also be considered so that the continuity equation for odd oxygen (eqn [6]) must also include terms to describe the transport. In reality, ozone is produced in a source region in the low latitude middle stratosphere and moved to higher latitudes, where ozone is slowly destroyed, by the action of the stratospheric general circulation.

For many years, it was thought that Chapman's model could adequately explain the distribution of stratospheric ozone, at least in the middle and upper stratosphere. However, with improved measurements – both in the laboratory and in the atmosphere – it became apparent that reaction [4] only removes about 25% of the odd oxygen produced by oxygen photolysis. Calculations based on just the Chapman reactions will seriously overestimate stratospheric ozone concentrations, even when the photochemical time constant is short.

Catalytic Cycles

Reaction [4] has an unexpectedly high activation energy for such an exothermic reaction. It was realized that, at stratospheric temperatures (200–290 K), odd oxygen could be removed efficiently in catalytic cycles, which achieve the same result as reaction [4] without loss of the catalytic species X or XO:

(i.e., the two reactions effectively catalyze reaction [4]).

Cycles of this kind were discussed for mesospheric chemistry by David Bates and Marcel Nicolet in the 1950s. In the late 1960s and the early 1970s attention switched to their role in stratospheric chemistry, pioneered by, for example, Harold Johnston, Paul Crutzen, Mario Molina, and Sherry Rowland, who all highlighted an important potential role in ozone depletion for these cycles. They showed that if the concentration of X increases, the ozone concentration would fall: ozone would be depleted.

There are a number of candidates for X present in the stratosphere. These include NO, H, OH, Cl, and Br, all discussed in detail in separate articles. Here, we will take the cycle involving the oxides of nitrogen (NO and NO_2 , members of the odd-nitrogen family) as a single example of odd-oxygen destruction by these catalytic cycles.

So, substituting X = NO in the catalytic cycle,

This cycle is responsible for about 50% of odd-oxygen removal from the stratosphere, despite a number of competing reactions of which the most important is NO_2 photolysis, very rapid even at low altitudes. This produces a 'null cycle':

Assuming steady state between NO and NO_2 based on reactions [8]–[10] (a very good approximation) then, after some simple algebra, the rate of odd-oxygen change by the nitrogen oxides can be written,

$$d([\text{O}] + [\text{O}_3])/dt = -2k_6[\text{NO}_2][\text{O}] \quad [11]$$

and the total rate of odd-oxygen change for the combined Chapman and odd-nitrogen cycles would be given by adding eqns [6]–[11]. Similarly, other cycles, where XCl, OH, etc., have loss rates of the form given by eqn [11]; the rate-limiting step usually involves the reaction of XO with atomic oxygen, O. The concentration of O is low in the low stratosphere (since the rate at which O recombines to form O_3 , reaction [2], increases with increasing pressure) and thus the odd-oxygen loss rates are lower in the low stratosphere, leading to the longer photochemical time scales there.

These cycles dominate the middle atmosphere away from polar latitudes. In polar latitudes severe ozone depletion has been observed in recent years, forced by halogen chemistry and with the halogens turned into active form by reactions on polar stratospheric clouds, at the low temperatures found there. The cycles are again catalytic and involve both ClO and BrO.

One final general point is worth making, again to be discussed in more detail in the articles discussing the individual

chemical families. This is that in addition to the radical species involved in the catalytic cycles, other family members exist and can play important roles. For example, HNO_3 is an important reservoir species for odd nitrogen; i.e., a species which is a 'holding tank' for NO and NO_2 (and indeed OH and HO_2) but does not take part in ozone-destruction cycles. Similarly, HCl and ClONO₂, the reservoirs for odd chlorine, are usually the dominant form of chlorine in the lower stratosphere, a fact that limits chlorine-catalyzed ozone destruction, away from polar latitudes, mainly to the upper stratosphere.

Synopsis

Halogen-containing compounds from Earth's surface that reach the stratosphere release their constituent atoms by exposure to ultraviolet light and oxidation. The halogen atoms, mainly chlorine and bromine, undergo a series of photochemical reactions that catalytically destroy ozone. Consequently, very small abundances of halogens produce dramatic losses of ozone, such as those observed over the polar regions in springtime and in the exhaust plumes of rockets fueled by chlorine-containing propellants. This article summarizes the interactions between the chemical substances that determine the abundances of the highly reactive halogen free radicals in the stratosphere and the catalytic reactions that destroy ozone.

Introduction

The potential impact of halogen atoms (fluorine, chlorine, bromine, and iodine) on the chemistry of stratospheric ozone (O_3) was first recognized in the early 1970s, not long after researchers proposed that nitrogen oxides (NO_x) and hydrogen oxides (HO_x) could destroy ozone. These halogen atoms are produced by compounds that are relatively unreactive in the troposphere but that decompose photochemically in the presence of shortwave ultraviolet radiation in the stratosphere. Among such compounds are those known as halocarbons, which are predominantly industrial in origin.

For much of the second half of the twentieth century, a number of halocarbons were used for a variety of purposes, including refrigeration, manufacturing of foam products, extinguishing of fires, fumigation of crops, and production of polymers. Organisms in the upper ocean produce small, but significant, amounts of several halocarbons. There are only a few ways to destroy most halocarbons once they are released to the atmosphere, including reaction with hydroxyl (OH) (if the halocarbon contains a hydrogen atom), ultraviolet photolysis, and reaction with electronically excited oxygen atoms, $O(^1D)$. However, these processes also initiate the cycle of ozone destruction in the stratosphere.

Halogen atoms are examples of free radicals, species that typically (although not exclusively) possess an odd number of electrons and require an additional electron to fill a molecular orbital to become more stable. Upon collision, a free radical can acquire this additional electron by stripping it from another molecule (called electron transfer), by pulling an atom off the collision partner (called extraction), or by attaching to another free radical (called addition or recombination). With a variety of collision partners available, there are literally hundreds of possible reactions and dozens of inorganic halogen compounds that must be considered for an accurate description of halogen chemistry in the stratosphere. However, only halogen atoms react rapidly with ozone. Thus, atmospheric chemists refer to two types of inorganic halogen species in the stratosphere, free radicals, and reservoirs. Whereas the free radicals are directly involved in ozone destruction, the reservoirs are more stable compounds that do not react directly with ozone. However, the reservoirs can react with other free radicals or break down in sunlight to form free radicals, hence the origin of their name.

Laboratory studies show that the reactivities of the families of halogen compounds follow the general trend $I > Br > Cl > F$; however, stratospheric abundances follow the trend $[Cl] > [F] > [Br] > [I]$. Consequently, most of the ozone destruction by halogens in the stratosphere is due to chlorine and bromine species. Destruction of ozone has been quantitatively linked to chlorine and bromine free radicals, whereas inorganic fluorine species have little impact on ozone. The role of iodine appears to be limited owing to small concentrations in reactive forms.

Gas-Phase Halogen Photochemistry

Halogen-containing organic compounds released at the Earth's surface, and that are relatively unreactive in the lower atmosphere, become mixed throughout the lower atmosphere, a process that takes about a year. When they reach the upper troposphere, these gases are slowly transported across the tropopause, primarily in the tropics. As air in the lower tropical stratosphere ascends, these source gases, which contain at least one halogen and one or more carbon atoms, are broken down by processes initiated by shortwave ultraviolet radiation. The halogen atoms that are released then react with ozone and other compounds to form inorganic compounds that contain only halogen, hydrogen, nitrogen, and oxygen atoms. If there is no selective separation (e.g., precipitation), the number-weighted sum of the mixing ratios of all forms of a particular halogen will be conserved. Thus, as the organic compounds break down in sunlight, the abundances of inorganic compounds increase concomitantly. Ultimately, the inorganic halogen compounds are removed from the stratosphere by slow downward transport into the upper troposphere at high latitudes. Because these compounds generally are acidic and water soluble (unlike the organic source gases), they are readily scavenged in the relatively wet troposphere, returning to the Earth's surface with precipitation.

Halogen atoms destroy ozone by a series of catalytic reactions, so called because the halogen free radicals are cycling between various forms with no net change in abundance while the ozone is converted into diatomic oxygen, O_2 . The main catalytic cycles for ozone destruction can be written symbolically (where X and Y represent F, Cl, Br, or I, $h\nu$ represents

a photon of wavelength c/ν , and M is shorthand for an N_2 or O_2 molecule) as follows:

Cycle one

Cycle two

Cycle three

The net result of each of these cycles is loss of two ozone molecules with no change in radical abundance as in eqn [VIII]:

From the law of mass action, the rate of ozone destruction by a catalytic cycle is the product of the concentrations of the reactants and the rate constant for the rate-determining step. Additional reactions (shown below) shift the steady-state balance between the two forms of the halogen radicals in favor of XO, such that the rate-determining steps in each of the three cycles above involve XO radicals. Consequently, we can write the change of ozone vs time as

$$\begin{aligned} \frac{-d[O_3]}{dt} &= 2(k_{III}[XO][O] + k_{IV}[XO][YO] + k_{VII}[XO][HO_2] \\ &\quad + \text{minor cycles}) \end{aligned} \quad [1]$$

The factor of 2 in eqn [1] appears because two ozone molecules are destroyed for each pass through a given cycle.

If there were no other reactions to consider, a significant amount of ozone would be destroyed before stratospheric air mixed back into the troposphere. However, the halogen radicals are deactivated by reactions with other species that are present. The main reactions of importance are shown in eqns [IX]–[XI].

There are also important reactions that rerelease the radicals or that produce short-lived reservoirs, including those shown in eqns [XII]–[XIV], [IVc].

Halogen oxides rerelease halogen atoms by reacting rapidly with nitric oxide (NO) produced by photolysis of NO_2 and the reaction $O + NO_2$. Nitric oxide thereby strongly influences the

Figure 1 Schematic diagram of gas-phase halogen cycling in the Earth's stratosphere. Open arrows are used for fast exchange between the radical forms of inorganic chlorine. Large dashed arrows represent transport across the tropopause. X and Y are halogen atoms, Cl, Br, I, or F. Processes that are underlined result in catalytic ozone loss. See text for further discussion.

partitioning between the atomic and diatomic halogen radical forms (eqn [XV]).

Except at very high solar zenith angles and at very low altitudes in the stratosphere, most of these reactions occur rapidly, and a steady state is established as the various chemicals cycle from one form to another. This cycling is shown symbolically in Figure 1.

Because the rates of the analogous reactions vary among the different chemical families, the partitioning between the different chemical forms also varies. HF is the main form of inorganic fluorine; HCl and $ClNO_3$ account for more than 90% of inorganic chlorine, except in the polar regions in winter; BrO, $BrNO_3$, and HOBr are the primary inorganic bromine species; and it is believed that IO, I, and HOI are the primary iodine species.

Heterogeneous Halogen Chemistry

Early studies of stratospheric halogens focused primarily on reactions between gaseous species, or so-called gas-phase chemistry; however, a new class of reactions was necessary to explain the rapid appearance of the Antarctic ozone hole in the

1980s. These reactions, called heterogeneous because they involve the interactions of species in different phases (e.g., between gases and species dissolved in liquids or solids), are typically less rapid than gas-phase reactions because they require the additional processes of adsorption and dissolution. However, under dim sunlight, such as in the winter polar regions or near the bottom of the stratosphere, where most ultraviolet light has been removed by the column of ozone overhead, the rates of heterogeneous reactions can become competitive with those of gas-phase reactions. It is also in these regions that ozone production is slow, such that ozone destruction cycles can have a large local impact.

Extensive laboratory and modeling studies have shown that the following heterogeneous reactions of inorganic halogens have the greatest impact on stratospheric chemistry (* denotes a reactant dissolved in liquid or solid phase):

These reactions convert relatively long-lived reservoirs of chlorine and bromine into species that photolyze readily in dim sunlight to release ozone-destroying radicals, and simultaneously convert short-lived reservoirs of NO_x radicals into long-lived species. Because NO_x limits the reactivities of the halogen compounds to ozone (e.g., reaction [XI], or reaction [XV] followed by reactions [IX] and [X]), its removal results in further enhancements of the halogen oxides, and consequently more severe ozone loss. The reaction

also indirectly enhances the abundances of halogen oxides by converting nitrogen oxides into the long-lived reservoir nitric acid.

Several of these heterogeneous reactions also influence the budget of HO_x by either producing (e.g., eqns [XVII] and [XIX]) or removing (e.g., eqns [XVIII] and [XX]) its short-lived reservoirs. Many of these heterogeneous reactions depend strongly on temperature, and become important in the lower stratosphere only when temperatures drop below about 210 K. Because of this, and the interactions of the halogen radicals with NO_x and HO_x , the response of ozone to changes in temperature or changes in abundances of the halogen source gases can be quite complicated and sometimes counterintuitive. Therefore, detailed computer models are required for accurate assessments of the impact of halogen species on stratospheric ozone.

Observations of Halogen Species

Direct observations of inorganic halogen species form the basis for descriptions of present, and prediction of future, decreases of ozone in the stratosphere. Based on the rate-determining step, it is sufficient to measure the species that control ozone loss (i.e., the halogen oxides) in order to compute the consequent rate of ozone destruction. However, to develop a more definitive understanding of the mechanisms controlling the abundances of the free radicals it is necessary to measure as

many of the inorganic halogen species as possible. Since the mid-1970s, there have been many observations of a large number of inorganic halogen species in the stratosphere. By the year 2000, the following species had been quantified in the stratosphere: fluorine family, HF, CF_2O , and CFCIO ; chlorine family, Cl, ClO, HCl, ClNO_3 , HOCl, OClO, and Cl_2O_2 ; bromine family, BrO, HBr, and BrNO_3 ; and iodine family, IO. The remaining species are predicted to exist at abundances that represent significant challenges for current measurement techniques. Each of the families is examined separately below.

Chlorine

Emissions of industrially produced halocarbons such as CFC-11 (CFCl_3) and CFC-12 (CF_2Cl_2) have delivered about three to four parts per billion of chlorine to the stratosphere, more than all the other halogen families combined. Emissions by volcanoes and solid rocket motors can significantly enhance the local abundances of inorganic chlorine, but otherwise these sources have a small global impact following diffusion and mixing. Equations [IX] and [X] proceed rapidly for chlorine, so that in the tropics and middle latitudes ClO rarely exceeds 20% of the inorganic chlorine budget. The remainder of the budget consists primarily of HCl and ClNO_3 in roughly equal proportions, except at very high altitudes where HCl dominates. This partitioning is illustrated schematically in Figure 2(a).

At high latitudes in winter, where photolysis rates are small and particles are larger and more abundant than at lower latitudes, heterogeneous reactions can activate all of the inorganic chlorine into short-lived reservoirs that rapidly produce radicals. Under these low illumination conditions, reactions such as [IVa] and [IVb] proceed rapidly for weeks and months, destroying ozone at rates of a few percent per day. In regions where ozone production is very slow owing to the lack of short-wavelength ultraviolet light necessary to break the O_2 bond, significant losses of ozone occur. When solar illumination increases in springtime, ozone loss will cease if nitric acid is present to produce NO_2 , which rapidly ties up ClO into ClNO_3 . However, if nitric acid is removed (as occurs annually over the Antarctic and occasionally over the Arctic by sedimentation of cloud particles that contain nitric acid and water, called polar stratospheric clouds, or PSCs), ClNO_3 and HCl re-form at rates that are far too slow to avoid complete destruction of ozone. In such regions, measurements have identified a clear correlation of ozone loss with enhanced abundances of ClO.

More typically, ozone production and loss are in closer balance, and only a gradual year-by-year erosion of ozone has been detected as abundances of the halogen species increase. Consequently, the impact of halogens on stratospheric ozone at midlatitudes and in the tropics is assessed by long-term monitoring of as many chemical species as feasible; these observations are incorporated into detailed photochemical models of the stratosphere for interpretation. Such studies indicate that trends in industrial chlorine and bromine compounds can account for at least half of the downward trends in column ozone abundances that have been observed over the past several decades. A great deal of international cooperation was necessary to formulate regulations (e.g., the Montreal Protocol) that have only just recently begun to impact

Figure 2 Midlatitude vertical profiles of the cumulative partitioning of (a) chlorine, (b) bromine, and (c) fluorine in the Earth's atmosphere from the ground to 40 km. Mixing ratios are typical of values in the 1990s. The slight falloff of total abundance with altitude in the middle to upper stratosphere reflects the lag time for air to reach these altitudes and the upward trends in source gas abundances in the 1990s. The partitioning of inorganic iodine is ignored because it is too uncertain at the present time.

the abundances of ozone-destroying forms of chlorine in the stratosphere.

Bromine

There are several sources of stratospheric inorganic bromine, including the halons and methyl bromide, the latter a compound that originates from both natural and industrial processes. Three inorganic bromine species, BrO, HBr, and BrNO₃, have been quantified in the stratosphere. BrO and BrNO₃ dominate the inorganic bromine budget. The abundances of the remaining species have been deduced by photochemical models and through the response of BrO to changing abundances of compounds with which it reacts. The partitioning of inorganic bromine is illustrated schematically in Figure 2(b).

It is believed that the sum of the abundances of all bromine-containing species in the stratosphere is around 20 parts per trillion (ppt), which is about a factor of 20 smaller than the sum of all the chlorine-containing species. However, the catalytic cycles involving bromine free radicals proceed much faster than their chlorine counterparts, and the percentage of bromine in free radical forms is larger than that of chlorine. Therefore, ozone destruction due to bromine is almost as significant as that due to chlorine, especially in the winter polar regions and in the lowermost stratosphere. However, because the natural sources of methyl bromide are not well characterized, and because there are still some important uncertainties in kinetics parameters, it is more difficult to attribute the anthropogenic contribution of bromine-catalyzed ozone losses. Consequently, international regulations for the industrial bromine compounds have taken longer to formulate than those for the chlorine compounds.

There have been some important developments in the study of atmospheric bromine based on new observations at the turn of the century that call into question some assumptions about the stratospheric bromine budget. First, by deploying grab samplers in the upper tropical troposphere, investigators have detected small, but significant, abundances of bromine-containing organic species that have fairly short lifetimes (days) in the troposphere. Presumably, these compounds are lofted to the upper troposphere by strong convective systems. Because abundances of these compounds vary widely at the surface, their contribution to the atmospheric bromine budget is hard to ascertain. These compounds have both natural and industrial origins, which further complicates assessments of anthropogenic ozone losses due to bromine. Second, observations have shown that large enhancements of bromine radicals occur sporadically near the Earth's surface in the polar regions by an uncertain, but probably heterogeneous, mechanism. It is possible that a similar mechanism operating in the lowermost stratosphere could alter the present understanding of bromine photochemistry. Third, elemental bromine has been detected in particles near the tropopause, raising questions about the sources and sinks of atmospheric bromine. New measurements in the atmosphere and laboratory will continue to improve our understanding of the impact of bromine on stratospheric ozone.

Iodine

Of all the halogens in the stratosphere, least is known about the iodine family. Laboratory measurements indicate that any organic iodine that is transported to the lower stratosphere will very quickly oxidize and release constituent atoms, and that these atoms will be even more destructive to ozone than chlorine and bromine. However, tropospheric measurements of potential source compounds suggest that the abundance of iodine in the stratosphere is on the order of 1 ppt or less, such that the iodine radicals will be at least an order of magnitude or smaller in abundance than BrO. Initial attempts to observe IO in the stratosphere have had mixed success, but generally indicate that there is no more than about 1 ppt of IO. However, little is known about the reactions that partition iodine into its various forms. It is likely that abundances of this species are highly variable.

There have been no attempts to measure other gas-phase inorganic iodine species whose concentrations are well below the detection limits of most modern instruments. However, the recent detection of elemental iodine in particles near the tropopause, an observation that is similar to the detection of elemental bromine, raises additional questions about the processes that control abundances of iodine in the atmosphere.

Even at low abundances, iodine could play an important role in ozone destruction in the lowermost stratosphere through its synergistic interactions with the bromine and chlorine free radicals. It has also recently been proposed that iodine could destroy ozone by reactions that involve OIO. Clearly, there is much to be learned about the role of iodine in the lower stratosphere.

Fluorine

Inorganic fluorine is produced by the photodecomposition of fluorocarbons, predominantly the chlorofluorocarbons (CFCs) CFCl_3 and CF_2Cl_2 . Measurements show that HF and the photodecomposition intermediates CF_2O and CFCIO can account for the entire inorganic fluorine budget, in agreement with models that incorporate laboratory measurements of fluorine reactions. Fluorine atoms react rapidly with hydrogen-containing species, especially H_2O and CH_4 that are present at part per million abundances in the stratosphere. In addition, there are no known ways to release fluorine atoms from HF, a very thermodynamically stable species. Consequently, immeasurably small abundances of fluorine radicals are present as extremely short-lived intermediates in the photodecomposition of fluorocarbons, and their contribution to ozone loss is negligibly small. Therefore, the primary role of fluorine in stratospheric chemistry is as a marker or tracer for other halogen species, in particular the CFCs. Ground-based and satellite measurements have shown that the rate of increase of HF in the stratosphere can be explained entirely by the buildup of CFCs in the troposphere followed by gradual transport into the stratosphere where they photodecompose in the presence of UV and chemical oxidants (primarily OH and $\text{O}(^1\text{D})$). The partitioning of inorganic fluorine is illustrated schematically in Figure 2(c).

Halogens and Ozone Loss

There are three distinct regimes in the stratosphere in which ozone losses have been attributed to halogens. These are the middle stratosphere year-round, in the Antarctic and Arctic polar vortices in springtime, and in rocket plumes within hours following launches. In all cases, two conditions are met that establish the link between halogens and ozone loss. First, the regions where ozone losses are detected are correlated with larger abundances of halogen radicals than in adjacent regions where there is less or no ozone loss. Second, the rates at which ozone losses occur are equivalent (within measurement uncertainties) to the corresponding rates predicted with models that include laboratory measurements of the rate constants for the rate-determining reactions. Examples of the anticorrelation between abundances of chlorine oxide and ozone are shown in Figure 3. The sources of enhancements in the chlorine radicals differ (direct local injection in the case of rockets, and heterogeneous reactions of HCl and ClNO_3 in the case of the Antarctic ozone hole). Consequently, the time-scales for ozone loss in these two cases are dramatically different, less than 1 h for the rocket plume and a month for the Antarctic ozone hole; however, in both cases the amounts of ozone destroyed over these periods are consistent with the known kinetics of the halogen radicals to within the uncertainties of the measurements.

In the two cases presented in Figure 3, the ozone destruction rates vastly exceeded the rates at which ozone could be replenished. Thus, regions of low ozone formed adjacent to regions of higher ozone where the abundances of the halogen free radicals were significantly lower. In the middle stratosphere, the situation is quite different, and ozone production and loss rates nearly match (i.e., ozone is in photochemical steady state). In addition, the spatial variability of the halogen radicals is small. Consequently, it is difficult to attribute an instantaneous ozone value to a particular abundance of halogen radicals. Rather, it is by correlating the long-term downward trend of ozone abundances with concomitant increases in halogen radical abundances that the link is deduced. Observations for the last 20 years of the twentieth century showed a decrease in ozone of approximately 10–15% between 35 and 50 km, an amount that agrees well with the decrease predicted as a result of the steady rise in abundances of stratospheric chlorine, the primary agent of halogen-induced ozone loss in the middle stratosphere.

Long-term reductions in ozone have been reported for other regions of the stratosphere, in particular the Arctic and the lowermost stratosphere at middle latitudes. In the first case, springtime ozone losses are consistent with calculations based on observed abundances of the radicals ClO and BrO. However, losses in the middle of winter appear to be significantly greater than expected, for reasons that are not yet clear. It is possible that transport between regions of differing ozone concentrations confounds efforts to attribute ozone loss to specific halogen radical abundances. In the midlatitude lower stratosphere, ozone losses are highly uncertain because they occur in a region where there is a strong vertical gradient in the ozone mixing ratio and because measurement techniques are not optimized for these altitudes. This is a region of the stratosphere where temperatures are very low ($\sim 200\text{ K}$) and

Figure 3 Examples of the measured correlation of ozone loss with ClO radical abundances in (a) the Antarctic ozone hole in 1987 (September 16) (excerpted with permission from Anderson, J.G., Toohey, D.W., Brune, W.H., 1991. Free radicals within the Antarctic vortex: the role of CFCs in Antarctic ozone loss. *Science* 251, 39–46. heterogeneous reactions on sulfuric acid aerosols or thin cirrus clouds could enhance halogen radical abundances. *In situ* observations in these regions have shown that chlorine radicals can be significantly enhanced to amounts that are sufficient to destroy ozone. However, the observations have been too infrequent and limited in geographical extent to link chlorine and bromine chemistry to ozone trends that have been inferred in the lowermost stratosphere. A renewed attention to halogen chemistry in the lowermost stratosphere promises to be very revealing.

Introduction

None of the anthropogenic carriers of halogens in the stratosphere is actually released there. They are emitted close to ground level and have to survive transport through the troposphere, requiring a lifetime in the atmosphere of at least a year. Thus soluble halogen-containing materials, such as hydrogen chloride (HCl), which are rained out of the atmosphere in a matter of days, do not provide a significant halogen input into the stratosphere; neither do the more reactive materials, such as trichloroethene or tetrafluoroethene, which are oxidized in the lower atmosphere within a similar time scale.

The bulk of the halogen input into the stratosphere is from anthropogenic gases that have atmospheric lifetimes significantly longer than 2 years. These are released from industrialized regions, principally in the Northern Hemisphere.

Chlorofluorocarbons (CFCs), with atmospheric lifetimes of 45–1700 years, were introduced in the 1930s as refrigerants that were safer than the toxic and flammable materials then used. Despite the fact that small amounts of CFCs have been measured in volcanic vents, the natural contribution is negligible compared with man-made sources. Carbon tetrachloride, which has an atmospheric lifetime of 35 years, had been used as a solvent until the middle of the twentieth century; subsequently it was mainly used as a raw material for CFC manufacture, and emissions into the atmosphere grew with CFC production. Hydrochlorofluorocarbons (HCFCs), with lifetimes between 1.4 and 19 years, were introduced in the 1940s for deep freezing applications otherwise served by ammonia. More recently, the HCFCs have become partial replacements for CFCs. Halons, fire-extinguishing chemicals with lifetimes of 11–65 years and containing bromine, were introduced in the 1960s. At the same time the use of methylchloroform (1,1,1-trichloroethane, atmospheric lifetime 4.8 years) as a precision cleaning solvent was expanding rapidly. Together with methyl chloride and methyl bromide, which have significant natural fluxes, these carry potentially reactive halogens (chlorine and bromine) into the stratosphere and, with the exception of methyl chloride, all are ozone-depleting substances controlled by the Montreal Protocol.

The history of anthropogenic emissions and the resulting atmospheric concentration is described here, together with the consequential rise of chlorine and bromine in the troposphere. CFCs, carbon tetrachloride, and most of the halons are removed from the atmosphere only by photolysis in the stratosphere, hence their relatively long atmospheric lifetimes. HCFCs, methylchloroform and methyl halides are oxidized in the troposphere and generally have shorter atmospheric lifetimes, but for all compounds the average time delay between

release in the lower atmosphere and decomposition in the ozone layer to generate stratospheric halogen is 3 years. Furthermore, the relative effectiveness in ozone depletion of each compound varies with the altitude at which its halogen is released, and this, together with the time delay, is taken into account when calculating the total Equivalent Effective Stratospheric Chlorine (EESC), which is a measure of the combined effect of all ozone-depleting substances.

Fluorine does not react with stratospheric ozone. Consequently, the hydrofluorocarbons (HFCs) that are designed to replace CFCs are not controlled under the Montreal Protocol. There is already a significant stratospheric fluorine concentration arising from decomposition of CFCs and this is starting to be augmented by HFCs, which have lifetimes between 1.5 and 240 years. The extent of this and the concentrations of the much less reactive perfluorocarbons (PFCs) are also discussed.

The Chlorine Flux

Chlorofluorocarbons

Most of the anthropogenic chlorine content of the atmosphere is a consequence of CFC emissions. Historically, the largest single source was aerosol spray cans from which the CFC propellant was released immediately the can was used. Currently, the principal release into the atmosphere is from a declining stock of CFC contained in refrigeration and air-conditioning systems and foam insulation; in these applications, release of the substance occurs some time after it was manufactured. The delay is variable. Automobile air conditioners can release all of their contents in a matter of a few years; on the other hand, a domestic refrigerator has a typical service life of 20 years and the CFCs it contains leak only when it is dismantled. Insulating foam can be in use for much longer, with only slow release until (and if) the foam is crushed. Uncertainties in estimates of the delay between manufacture and emission into the atmosphere, characteristic of such uses, contribute significantly to the uncertainty of the estimated emission.

For almost 30 years the manufacturers of CFCs have organized an annual collection of audited industrial production and sales data for CFC-11 and CFC-12. Historical production and sales records were also extracted by the manufacturers for the period back to first production in 1931 and the combined data provide the basis for calculation of emissions of these compounds. Annual emissions are estimated for each major category of application based on the quantities used, coupled with emission functions that take account of the rates of release of the materials during actual use and disposal (which are specific to the application). The survey procedure and

emissions estimation have been extended to most of the industrial halocarbons:

- CFC-11 (trichlorofluoromethane), principally used in aerosols and foam insulation
- CFC-12 (dichlorodifluoromethane), principally used in aerosols and refrigeration
- CFC-113 (1,1,2-trichlorotrifluoroethane), a solvent
- CFC-114 (1,1,2,2-tetrafluorodichloroethane), principally used in aerosols and refrigeration
- CFC-115 (chloropentafluoroethane), a refrigerant.

In much of the world, CFC production was carried out by subsidiaries of companies that reported their production and sales into the database and up to 15 years ago the only producing country not included was the USSR. Since then India, China, and Korea have become significant producers, although they too do not report into the industrial database. However, national aggregate CFC production now has to be reported to the Secretariat of the Montreal Protocol by all parties. The estimated historical quantities released, shown in **Table 1**, are based on a composite global estimate of annual production from the industrial and legislative databases.

For each sales category a characteristic pattern of emissions in time was established by market surveys carried out by the producers. This enabled estimates of annual emissions as

outlined above. These have been the subject of a sensitivity study that confirmed that the largest contributions to the uncertainties came from the fraction of production that was not reported in the industrial data and the rate of release of materials from closed-cell foams. The first of these has been addressed using the database from the Montreal Protocol, which now matches the industrial data reliably (to within 1% over the same set of countries). The second is a particular problem for CFC-11, where the range of emissions resulting from the lowest credible estimate of the release from closed-cell foams to the highest is 13.1%. For the period up to 1992, a mid-range estimate was used in **Table 1**. In recent years, as the degree of containment of CFCs in systems has improved, the historical emissions functions have tended to overestimate releases. This was allowed for in the estimates developed for recent Scientific Assessments and, from 1992 onwards, it is those values that are shown in **Table 1**.

In all cases the release estimates show substantial falls during the 1990s. The fall in consumption has actually been faster than that required under the Montreal Protocol; nevertheless, large quantities of CFCs remain in systems and may be released in the future: for example, over 700 Gg of CFC-11 and 250 Gg of CFC-12 are currently unreleased.

Figure 1 shows how the atmospheric concentrations of CFCs have grown. These were calculated using a simple single-box

model of the atmosphere and current estimates of atmospheric lifetimes, according to eqn [1], where C_0 and C_y are the atmospheric concentrations in the starting year and in year y , S is the annual rate of release of the substance, and T is its atmospheric lifetime.

$$C_y = ST + (C_0 - ST) \exp(-y/T) \quad [1]$$

The units are parts per trillion (ppt, 1 in 10^{12}) of tropospheric chlorine loading, which is the calculated concentration of each CFC multiplied by the number of atoms of chlorine in its molecule. Thus, for CFC-11 (fluorotrichloromethane), the CFC concentration is multiplied by 3.

While the growth in chlorine loading arising from CFC-12 emissions has slowed in recent years, it is still the largest of the CFC contributors and its absolute concentration is still growing. The concentrations of CFC-11 and CFC-113 have fallen discernibly, and those from CFC-114 and CFC-115 are not large enough to matter. Overall, the CFC contribution to chlorine loading is now level in time.

Chlorocarbons

The next largest contribution to the chlorine loading of the atmosphere comes from carbon tetrachloride (CCl_4 , tetrachloromethane) and methylchloroform (CH_3CCl_3 , 1,1,1-trichloroethane). Estimates of their emissions are shown in Table 2.

Carbon tetrachloride is hepatotoxic at relatively low concentrations and so has not been used as a solvent in developed countries for many years. Its principal use is as raw material for the manufacture of CFC-11 and CFC-12 and it is thought that the accumulation in the atmosphere now results solely from process losses. It has not been possible to quantify these losses in the same way as for the CFC releases, consequently emissions into the atmosphere have been calculated from the change in atmospheric concentration over the period 1979 to 1996, using an inverted form of eqn [1].

For methyl chloroform, an audited production and sales database has been maintained from information collected by the producers in much the same way as for CFCs. With the

exception of use as a chemical intermediate (in which it is totally converted and not released), methyl chloroform was used as an industrial solvent, with total emission into the atmosphere. Hence the emission function is relatively simple; 3/4 of annual sales are estimated to be emitted in that year and 1/4 in the following year. Long-term storage, over one or two years, was accommodated by a linear displacement of emissions in time. Prompt emissions, coupled with a relatively short atmospheric lifetime, have meant that the concentration of methyl chloroform shows the sharpest fall as a consequence of the Montreal Protocol. Figure 2 shows the contributions to chlorine loading from the individual chlorocarbons superimposed on that from the CFCs.

Hydrochlorofluorocarbons

Despite their potential to replace CFCs, hydrochlorofluorocarbons (HCFCs) have relatively little impact on atmospheric chlorine loading. The principal member of this group of substances, chlorodifluoromethane (HCFC-22), has been used as a refrigerant fluid since 1946; its low boiling point

Figure 2 Contributions to tropospheric chlorine loading from CFCs and chlorohydrocarbons: (a) methyl chloroform (1,1,1-trichloroethane); (b) carbon tetrachloride (tetrachloromethane); (c) all CFCs combined, as shown in Figure 1.

makes it suitable for low-temperature duties and some air-conditioning. As shown in Table 3, HCFC-22 emissions have grown to about 250 Gg y^{-1} and are now stable. Emissions of the other HCFCs are one or two orders of magnitude lower. HCFC-124 (1,1,1,2-tetrafluorochloroethane), introduced comparatively recently, is an aerosol propellant and refrigerant

fluid that is produced in modest amounts. HCFC-141b (1,1-dichloro-1-fluoroethane), again a relative newcomer, is produced in much larger quantities for use either as a blowing agent for rigid plastic foams, such as those used for insulation, or as a solvent. HCFC-142b (1-chloro-1,1-difluoroethane) is also used to blow plastic foam. Over 94% of all HCFC production is in the developed world.

HCFCs were considered to be suitable temporary replacements for CFCs because of their low intrinsic potential to impact the ozone layer. In general, they contain less chlorine than CFCs, have shorter atmospheric lifetimes, so that they do not accumulate in the atmosphere to the same extent as CFCs, and are not photolyzed as effectively in the stratosphere, so that the chlorine they contain is not released directly into the ozone layer. Nevertheless, HCFCs are ozone-depleting substances and are to be phased out under the Montreal Protocol by 2020 in the developed world and 2040 elsewhere. The contribution of HCFCs to chlorine loading is shown in Figure 3; no allowance has been made for the relative effectiveness of their chlorine content.

Natural Source of Chlorine

Although the quantities released by human activities are small, methyl chloride (CH_3Cl , chloromethane) is produced

by natural processes in sufficient amounts to contribute significantly to stratospheric chlorine. The lifetime of methyl chloride is only 1.3 years. However the flux of 4 Tg y^{-1} , mainly from the oceans, biomass burning, and terrestrial fungi, is large enough to maintain an atmospheric concentration of 550 ppt.

The Bromine Flux

Halons

The natural contribution to bromine in the stratosphere is similar to that from anthropogenic sources; of the total bromine loading of about 17 ppt, 9 ppt is attributable to man's activities and most of this comes from halon emissions. Halons were first produced as fire-extinguishing agents in 1963 and their use expanded to almost 20 Tg y^{-1} by the mid 1990s. Two substances predominated; Halon-1211 (bromochlorodifluoromethane), used mainly in portable extinguishers, and Halon-1301 (bromotrifluoromethane), an agent used in fixed systems. In addition, Halon-2402 (1,2-dibromotetrafluoroethane) was produced in somewhat smaller quantities and used in Eastern Europe. Halon-1202 (dibromodifluoromethane) has also been detected in small, but growing, amounts in the atmosphere.

Bromine is 60 times more potent in ozone depletion than chlorine in the current background stratospheric composition. This was recognized in the Montreal Protocol and halon production was phased out earlier than CFCs in the developed world (in 1994). However, production of Halon-1211 and Halon-1301 will continue in China, India, and Korea for the next few years and Russia has dispensation to continue the manufacture of Halon-2402.

In much the same way as for CFCs, audited production statistics are available from industry in the developed world and from the submissions required under the Montreal Protocol for the controlled halons, but the proportion of annual halon production that is unreleased is much higher than is the case for CFCs. Currently, halons should be released into the atmosphere only when they are used in earnest – on a fire or when the fire protection system is activated. Although

historically they were also released during training and system testing, there remains a considerable time delay between production and release and a stock of halon (known as the 'bank') has accumulated in systems and equipment. The emissions of Halon-1211 shown in Table 4 were based on a small part of the bank (currently 12%) being emitted each year. In the case of Halon-1301, calculated similarly, the emission factor is now 4% of the bank each year.

Production data for Halon-2402 do not exist in the same form and so the values for emissions in Table 4 were calculated by inverse modeling from measured atmospheric concentrations, using eqn [1]. The source of Halon-1202 has yet to be identified, although it is a well known by-product of the manufacture of Halon-1211. The emissions shown in Table 4 were calculated by inverse modeling.

Methyl Bromide

Methyl bromide contributes a total of 10 ppt to bromine loading. Of this, only about 1.9 ppt arises from human activities that are controlled under the Montreal Protocol, principally use of manufactured material for pest control in growing and harvested agricultural produce. Minor other anthropogenic sources that are not controlled add a further 0.4 ppt into the atmosphere; these include the exhausts of motor vehicles running on leaded gasoline and also chemical process emissions.

Although there is much uncertainty, the bulk of methyl bromide entering the atmosphere seems to come from natural processes. The role of the oceans is particularly difficult to untangle because they act as both sources and sinks. Methyl bromide is released into the atmosphere particularly from the polar oceans and is absorbed from the atmosphere into tropical waters where it is destroyed by bacteria.

A number of other bromine compounds are produced naturally: dibromomethane, bromochloromethane and dibromochloromethane together can add up to 6 ppt to bromine loading at ground level, particularly in the Arctic. However, these are very short-lived species and are not considered normally to be transported into the stratosphere.

Figure 4 shows the increase in anthropogenic bromine loading since 1970, subdivided into contributions from individual compounds. In the absence of better information, the contribution from methyl bromide has been shown as constant.

The Fluorine Flux

Neither F nor CF_3 radicals, nor their oxygenated derivatives, interact with stratospheric ozone; fluorine released into the stratosphere is converted into hydrogen fluoride (HF), which does not react further and is eventually removed when the stratospheric air circulates into the troposphere. However, it is a significant component of the stratospheric halogen budget. In much the same way as for chlorine and bromine, fluorine loading of the troposphere may be calculated from the atmospheric concentrations of CFCs, HCFCs, and halons, with the results shown in Figure 5. The contribution from hydrofluorocarbons (HFCs) is currently small but is increasing at

Journal of Geophysical Research 104: 15985–15999.

Figure 4 Contributions to tropospheric bromine loading from (a) that part of methyl bromide emissions that is controlled under the Montreal Protocol; (b) Halon-1202 (dibromodifluoromethane); (c) Halon-2402 (1,2-dibromotetrafluoroethane); (d) Halon-1301 (bromotrifluoromethane); (e) Halon-1211 (bromochlorodifluoromethane).

a significant rate. This is largely a consequence of releases of trifluoromethane (HFC-23, fluoroform), which is a by-product of the manufacture of HCFC-22, has a long atmospheric lifetime, and is decomposed in the stratosphere, so adding to the

Figure 5 Contributions to tropospheric fluorine loading from (a) all halons; (b) all HCFCs; (c) all CFCs.

fluorine burden there. More recently this has also been augmented by releases of HFC-134a (1,1,1,2-tetrafluoroethane, $\text{CF}_3\text{CH}_2\text{F}$), which is manufactured for use as a refrigerant and now has a tropospheric concentration of 9 ppt.

Other fluorine-containing substances do not contribute significantly to fluorine loading either because the quantities released are currently too small to matter (the case with hydrofluorocarbons other than HFC-23 and HFC-134a) or

because they are so inert that they do not decompose to release fluorine in the stratosphere (the case with perfluorocarbons and sulfur hexafluoride).

Perfluorocarbons, in particular those that are formed as by-products of primary aluminum production, are much more abundant than hydrofluorocarbons. Tetrafluoromethane (CF_4 , PFC-14) has now reached a concentration of 80 ppt, half of which is due to aluminum production. The other 40 ppt is volcanic in origin and has accumulated in the atmosphere over many thousands of years. Hexafluoroethane (C_2F_6 , PFC-116), another aluminum by-product, has no natural source and its atmospheric concentration now stands at 3 ppt. These substances have atmospheric lifetimes over ten thousand years and are so inert that they do not contribute to the stratospheric loading of fluorine; indeed, the trend of their stratospheric concentrations with altitude is a good indicator of their historic tropospheric concentrations.

As for perfluorocarbons, the atmospheric lifetime of sulfur hexafluoride (SF_6) is long (3200 years) and it too does not contribute to the stratospheric loading of fluorine. Although there is a volcanic source, it is too small to be significant and most of the 4 ppt of sulfur hexafluoride that is now present in the atmosphere has been used in industrial applications such as electrical switchgear.

Equivalent Effective Stratospheric Chlorine and the Future

The concentrations so far discussed may be verified by direct measurement of the individual species in the troposphere, which is comparatively well mixed. Tropospheric loading describes the concentration of potentially active chlorine and bromine in the flux of air entering the stratosphere; it is not exactly equal to the loading of active halogen at the ozone layer. This is parameterized by equivalent effective stratospheric chlorine loading (EESC). To calculate the EESC, the tropospheric loadings of all compounds are adjusted by an overall factor to take account of the transport time between the troposphere and the stratospheric ozone layer and the contributions from individual chlorine- and bromine-containing compounds are adjusted by factors that accommodate their different effects on the ozone layer. The delay due to transport is set at 3 years. The effectiveness factor for the difference between chlorine and bromine is set at 60, as described above. The differences between individual chlorine compounds are much smaller than that; they range from 1.11 for HCFC-123 (CF_3CHCl_2) to 0.35 for HCFC-22 (CF_2HCl).

Figure 6 shows the way that EESC has developed in the past and the changes expected over the twenty-first century.

Figure 6 Contributions to the equivalent effective stratospheric halogen loading from (a) halons and controlled sources of methyl bromide; (b) all HCFCs; (c) controlled chlorocarbons; (d) all CFCs; and (e) methyl chloride and the natural (and other uncontrolled) sources of methyl bromide.

Although it is clear that the peak loading is past, it will take the whole of the twenty-first century for the stratospheric loading to return to 1970 levels and, all other things being equal, the return to loadings that predate the Antarctic ozone hole is expected to occur only towards the middle of the century.

Synopsis

Anthropogenic halocarbons such as chlorofluorocarbons, CCl_4 , and CH_3CCl_3 are largely responsible for the observed depletion of stratospheric ozone, yet there is a contribution by gases that are both naturally and anthropogenically produced. Of the naturally produced halocarbons, CH_3Br and CH_3Cl are the largest contributors to stratospheric ozone depletion, accounting for about one-quarter of the equivalent chlorine in the atmosphere. Other shorter-lived halocarbons, such as CHBr_3 and CHCl_3 , may also be contributing, particularly as Earth's climate changes and alters their natural cycles. These shorter-lived gases also play an important role in tropospheric chemistry of the marine boundary layer.

Introduction

The depletion of stratospheric ozone (O_3) has been driven by long-lived, anthropogenic halocarbons emitted into the atmosphere during the past few decades. When these gases, which in large part resist degradation in the troposphere, reach the stratosphere, their halogen atoms are released as free radicals. Here, the radicals accelerate the removal of ozone through a series of catalytic reactions. Fluorine and iodine do not contribute significantly to stratospheric ozone depletion. Fluorine radicals are removed effectively in the stratosphere, and iodinated compounds react readily in the troposphere. Therefore, persistent halocarbons containing chlorine and bromine are the main halogenated compounds implicated in the destruction of stratospheric ozone, and chlorine and bromine radicals are the primary halogens of concern.

Not all halocarbons in the atmosphere are entirely anthropogenic. Although attention in atmospheric chemistry has centered on halocarbons resulting from human activities, the chlorofluorocarbons (CFCs), halons (CBrF_3 , CBrClF_2), chlorinated solvents (CH_3CCl_3 , CCl_4 , CH_2Cl_2 , CHCl_3), and their replacements, the hydrochlorofluorocarbons (HCFCs), and the methyl halides (methyl chloride (CH_3Cl) and methyl bromide

(CH_3Br)) are present in significant amounts in the troposphere (Figure 1). Other halogenated methanes, such as CHBr_3 , CH_2Br_2 , and CH_3I , can be locally high in atmospheric concentration, but their short tropospheric lifetimes significantly reduce their impact on stratospheric ozone. Nevertheless, halogen atoms from short-lived compounds do at times reach the stratosphere, likely through deep convection of these compounds. The contribution of these gases of lower concentration to ozone depletion is unknown, although considered by most to be small.

Of the naturally produced halocarbons, CH_3Br and CH_3Cl are the largest contributors to stratospheric ozone depletion, accounting for about one-quarter of the equivalent chlorine in the atmosphere (Figure 1). Methyl bromide is the single largest carrier of bromine to the stratosphere. Bromine, on a per-atom basis, is about 50 times more effective in depleting ozone than is chlorine. Although natural sources are the largest contributor to the methyl bromide budget, there was a sizable anthropogenic flux to the atmosphere through its use as a fumigant. By multilateral international agreement, its industrial production is being phased out largely because of its high ozone depletion potential. At this time, only critical uses such as quarantine and preshipment (QPS) fumigation are allowed (Figure 2). Methyl

chloride, on the other hand, is the most abundant chlorine-containing compound in the atmosphere, contributing over 15% to the total tropospheric burden of organic chlorine. Its sources are believed to be largely natural and there is some evidence that it was present at over 90% of today's levels during the early twentieth century. Both of these methyl halides have lifetimes of around a year, making them much shorter-lived than the CFCs, solvents, and halons currently banned by international agreement. Nevertheless, their large fluxes into the atmosphere mean that some fraction of their emissions can reach the stratosphere, where they become involved in ozone depletion.

Methyl Bromide

Methyl bromide is present in the atmosphere at a mole fraction, or volume mixing ratio, of around 7 parts per trillion (1 ppt = 1×10^{-12} mol of specific gas per mole of air) (Figure 2) and its known natural sources include the

ocean, biomass burning, fungi, salt marshes, wetlands, rice paddies, mangroves, and tropical rain forests (Figure 3). Methyl bromide has an added anthropogenic source from fumigation uses (agricultural, structural, and QPS). While the non-QPS anthropogenic emissions have been phased out as a result of the Montreal Protocol and its Amendments, the QPS anthropogenic sources remain for CH_3Br (Figure 2). The removal processes for CH_3Br include reaction with hydroxyl radicals (OH) in the troposphere, degradation in the oceans and soils, and photolysis in the stratosphere.

Until the 1990s, little attention had been paid to this gas in the atmosphere, in part because of its low mixing ratio and short atmospheric lifetime. In the early 1990s, atmospheric methyl bromide was thought to emanate naturally from a large oceanic source and to be destroyed exclusively by reactions in the atmosphere. Anthropogenic emissions, mainly from disinfection of soils, commodities, and structures, were considered responsible for about 3 ppt of CH_3Br in the atmosphere. Biomass burning and emissions from burning of leaded gasoline were thought to be the possible contributors, but were not quantified at that time. Recognizing that there was a paucity of information on this important atmospheric gas, scientists began working to understand more completely its cycling and atmospheric budget. The results were surprising in a number of areas.

The first of these surprises was that the ocean was not the large source it was thought to be, but rather a small net sink for atmospheric CH_3Br . This net sink, however, results from rapid aquatic production and degradation working in opposition in the surface ocean, leaving it largely undersaturated. In some areas where production exceeds degradation, the ocean is supersaturated in methyl bromide, but in most of the surface ocean, most of the time, methyl bromide is undersaturated. Because the degradation rate of CH_3Br is so high in most of the surface ocean, it had to be included as a significant component of the atmospheric lifetime computation. Subsequent calculations of the atmospheric lifetime of CH_3Br yielded a rate that was almost equal to the loss due to reaction with OH in the troposphere. This alone lowered the atmospheric lifetime of CH_3Br from around 2 years to 1 year.

At about the same time, studies of the terrestrial environment revealed additional sinks and sources of atmospheric CH_3Br . The discovery that CH_3Br was degraded rapidly in a variety of soils, mainly by prokaryotic bacteria, lowered the estimates of atmospheric lifetime even further.

Our current understanding of atmospheric CH_3Br is that of a gas with numerous, diverse sources and significant sinks on land, in the ocean, and in the atmosphere. Its lifetime, including atmospheric, oceanic, and soil sinks, is now computed at 0.8 year, but its calculated atmospheric budget is largely out of balance, with sinks outweighing sources. New findings continue to reveal previously unidentified sources, which seem gradually to be closing the gap between calculated sources and sinks (Figure 3).

Anthropogenic emissions of CH_3Br were scheduled for phaseout by 2005 in developed countries and 2015 in developing countries. The atmospheric concentration of this gas has responded to these reductions in emissions, decreasing from the high of about 10 ppt in 1995 to about 8 ppt in 2012 (a 20% reduction). As the anthropogenic contribution decreases,

Figure 3 Source and sink fluxes of methyl bromide (1996 and 2010) and methyl chloride.

the natural emissions become relatively more influential in stratospheric ozone depletion (Figure 3).

Methyl Chloride

Like methyl bromide, methyl chloride, at roughly 540 ppt in the atmosphere, received little attention until the mid-1990s, as most research efforts were directed toward the rapidly increasing anthropogenic halocarbons. Methyl chloride also has a short atmospheric lifetime, ~ 1 year, relative to the anthropogenic halocarbons and its anthropogenic sources are very small (Figure 3). Until recently, it was thought that most of the global emissions of CH_3Cl came from the oceans. Although the oceans are still considered a major source of CH_3Cl , new and more detailed studies show that the oceanic source is responsible for at most 15–20% of the methyl chloride in the atmosphere. Similarly, wood-rotting fungi contribute only a small amount and anthropogenic emissions of CH_3Cl and constitute only about 1% of the total budget. While biomass burning is another substantial source of CH_3Cl , there remains a sizable deficit in the overall budget. Studies have suggested that emissions from tropical plants could potentially make up this deficit; however, total emissions from this source have not been quantified. The identified sinks for methyl chloride, mainly loss via reaction with OH in the troposphere, suggest that about half of the CH_3Cl in the atmosphere is unaccounted for.

Other Gases

Most of the remaining naturally produced organic halogens are of low concentration and short lifetime. They are therefore thought to pose only a small threat to stratospheric ozone. However, they have been observed at the tropopause (Table 1) and they can be convected rapidly from the Earth's surface into the upper troposphere and lower stratosphere. Of the purely chlorinated gases, chloroform (CHCl_3) and perchloroethylene (C_2Cl_4) appear to have significant natural sources, although their budgets have been little studied. The naturally occurring brominated species (e.g., CHBr_3 , CH_2Br_2 , CHBr_2Cl), although low in concentration, are of some concern because of the efficiency of bromine in depleting stratospheric ozone. These gases are produced in the ocean and are supersaturated throughout, by tens to hundreds of percent. Together, these lesser gases represent most of the total flux of organic bromine into the troposphere (Table 2).

Closing the Budgets

From recent research, it is clear that the missing sources of methyl bromide and methyl chloride are not oceanic. The saturations of these gases have now been mapped over most of the oceans. While the ocean has become a small net source of methyl bromide as the anthropogenic sources have been phased out, its emission and the lifetime relative to the

Table 1 Organic bromine in the troposphere

Compound	Compound mole fraction $\times 10^9$	Bromine mole fraction $\times 10^9$
CH ₃ Br	10	10
CBrF₃	2.3	2.3
CBrClF ₂	3.5	3.5
C₂Br₂F₄	0.45	0.9
CH ₂ Br ₂	0.75–1.5	1.5–3
CHBr ₂ Cl	0–0.5	0–1
CHBr ₃	0.5–4	1.5–12
CH ₂ BrCl	0–0.5	0–0.5
CHBrCl₂	0–0.5	0–0.5
Total	>17.5	>19.7

Purely anthropogenic compounds appear in bold. Compounds that are natural or have significant natural components to their budgets (e.g., CH₃Br) are shown in normal.

Table 2 Potential global bromine fluxes

Compound	Source	Flux (Gmol Br year ⁻¹)
CH ₃ Br	Anthropogenic	0.5
CH ₃ Br	Natural	1.0
CH ₂ Br ₂	Ocean	2.0
CHClBr ₂	Ocean	1.5
CHBr ₃	Ocean	2.0
CH ₂ BrCl	Ocean	0.5
CBrClF ₂	Anthropogenic	0.05
CBrF ₃	Anthropogenic	0.012
C ₂ Br ₂ F ₄	Anthropogenic	0.005
Total		7.5 (6.0)

ocean degradation have not changed over the course of the phaseout. The magnitude of the missing sources has also remained fairly constant from before the phaseout through today (2013). Together, these suggest that the missing sources are not from the ocean or an underestimate of the fraction of emission from the fumigation uses. The ocean also is insufficiently supersaturated in methyl chloride to explain more than a small percentage of its total flux to the atmosphere. Further, although the atmospheric mixing ratios of both gases show marked seasonal cycles, the cycles in the Northern Hemisphere are amplified over those in the Southern Hemisphere, particularly for methyl bromide. Although tropospheric OH is responsible in part for the seasonal cycling, the uneven match between hemispheres, especially with smaller amplitude in the Southern Hemisphere, speaks for a more complicated involvement of sources and sinks. Because fluxes from the ocean to the atmosphere are retarded significantly at the ocean surface, it is not possible for cycles in the oceanic flux to drive significant seasonal variations in the atmosphere.

This has led to several studies to determine whether methyl halides are released in significant amounts elsewhere, and it appears that they are. A number of investigations have shown that natural and cultivated terrestrial plants emit both of these gases, and others as well.

The emissions seem to be related to the amount of halide in the soil. Coastal plants, such as those in salt marshes and in tropical environments, emit large quantities of methyl halides and, although their global area of coverage is small, they seem to contribute significantly to the global budget. To date, only a few plants and a few ecotypes have been studied for emission of methyl halides. Additional investigations are likely to locate more sources from the terrestrial biosphere, and with this a possible closing of the atmospheric budgets of these gases.

Although the natural fluxes of these gases existed long before there were problems with stratospheric ozone depletion, this does not mean that they are not important. Contributions of bromine and chlorine from the anthropogenic gases are now declining and should continue to do so into the future; this should provide some relief, albeit slowly. If the fluxes of natural compounds remain the same and all countries abide by the Montreal Protocol and its Amendments, then 'preozone-hole conditions' could be reached by the mid-twenty-first century. However, everything may not remain the same. A question that will become more pressing with global change is, "How will the fluxes of methyl bromide, methyl chloride, and other halogenated gases between the Earth's surface and atmosphere change in the future?" A change in sea surface temperature or soil temperature will certainly affect the fluxes, as will changes in precipitation or land use patterns. It is possible that such alterations of natural fluxes could offset or delay the timing of recovery, but we cannot know until we more fully understand the natural cycles of these ozone-depleting gases.

Introduction

The hydrogen radical family (HO_x) consists of the hydrogen (H), hydroxyl (OH), and hydroperoxyl (HO₂) radicals. Concentrations of these highly reactive radicals are small, between 1 part per trillion (ppt) in the lower stratosphere and 400 ppt in the upper stratosphere. Despite this, HO_x is important because it participates in many reactions that control the photochemistry of stratospheric ozone. The hydrogen radicals are important in the removal of O₃ through direct reaction with O₃ and indirectly through reaction with the halogen oxides. HO_x also removes ozone through reactions with the nitrogen and halogen chemical families. The extensive coupling of HO_x to these chemical families leads to a particularly complex set of reactions that control HO_x photochemistry. Understanding these mechanisms is important in understanding both HO_x and, more broadly, the mechanisms that control ozone photochemistry.

HO_x Sources

HO_x is produced from the oxidation of the stable hydrogen-containing species, water, methane, and molecular hydrogen. The relative strength of these sources is largely determined by their concentrations at the tropopause: H₂O ~4 parts per million (ppm), CH₄ ~1.5 ppm, and H₂ ~0.5 ppm. The numerous pathways that participate in this oxidation are diagrammed in Figure 1. The oxidation occurs mostly through gas phase reactions with highly reactive species, i.e. excited oxygen atoms, chlorine atoms, and OH. The oxidation of water also occurs via hydrolysis reactions catalyzed by acid aerosols

found in the lower stratosphere. In most cases, the production mechanisms include a large number of reactions, most of which have little direct effect on HO_x. These mechanisms are presented in terms of reaction sequences that can be simplified in terms of rate-determining reactions and net yields.

Gas Phase Processes

The largest single source of HO_x throughout the stratosphere is the oxidation of H₂O by the electronically excited oxygen atom O(¹D) which is generated from the photolysis of O₃ at wavelengths less than ~330 nm. The production from this mechanism is represented by a sequence of reactions that leads to a net conversion of H₂O to HO_x:

Only a small fraction of the O(¹D) produced from reaction [1] subsequently reacts via reaction [2]; most O(¹D) relaxes to ground state O(³P) after collisions with N₂ and O₂. The rate of this sequence is determined by the slowest or the 'rate-determining step', in this case reaction [2]. The rate of the production of HO_x from H₂O, which is equal to twice the rate of reaction [2], is shown in Figure 2. This and the following sequences are identified in the figures by the rate-determining steps.

The oxidation of methane requires a greater number of reactions to liberate all four hydrogen atoms. The sequence initiated by O(¹D) can produce as many as four HO_x:

Figure 1 Primary sources and sinks of HO_x are shown. Gas phase reactions are denoted with solid lines and heterogeneous reactions with dashed lines.

Figure 2 Typical mid-latitude daytime production rates of HO_x calculated from concentration profiles of the source gases are shown versus altitude. The CH₄ oxidation sequences initiated by O(¹D), OH, and Cl are grouped together. Likewise, the hydrolysis reactions involving N₂O₅, ClONO₂, and BrONO₂ are combined. The production from H₂ is less than 4% of the total at all altitudes.

An alternate pathway for the photolysis of CH₂O in reaction [9] is the production of H₂ and CO:

When the oxidation of methane follows this path, the net yield is only 2HO_x for every CH₄ consumed. Since reactions [9] and [11] compete, the yield of HO_x from CH₄ oxidation initiated by reaction [3] is somewhere between 2 and 4. The utility of the rate-determining step and net yields is particularly evident in this sequence, where nine reactions can be thought of in terms of one. In this case, the rate of production of HO_x from CH₄ is 2–4 times the rate of the rate-determining step, reaction [3]. The rate of this and the following CH₄ oxidation sequences decrease relative to the H₂O source at higher altitudes. This results from the net conversion of CH₄ to H₂O as the air in the lower stratosphere ages during the slow ascent into the mid to upper stratosphere.

The methane oxidation sequence that is initiated by OH is autocatalytic. OH is consumed at the initiation step,

but the subsequent reactions [4], [5], [6], [7], [8], [9] and [10] can produce as many as 2HO_x. In the lower stratosphere where the oxidation of CH₄ is most important, the rate of reaction [12] is faster than that of reaction [3], so that the sequence initiated by OH is often more important than that initiated by O(¹D).

Oxidation of CH₄ is also initiated by reactions of CH₄ with Cl.

The methane oxidation sequence that is initiated by Cl can be the most important source of HO_x in the winter polar vortex when active chlorine levels are high and HCl concentrations are low. In these conditions, ClO controls the conversion of CH₃O₂:

Outside the winter polar vortex this sequence is not a large source of HO_x, because Cl concentrations are lower and the reaction

is important, resulting in a lower yield for HO_x production. In these conditions [13] and [15] are the dominant production and loss terms of HCl.

The production of HO_x from the oxidation of H₂ is analogous to that of H₂O:

This source is much smaller than the H₂O and CH₄ sources, owing to the much lower concentration of H₂ in the stratosphere and to a smaller rate constant. In the lower stratosphere where this sequence is most significant, H₂ accounts for only 4% of the total production of HO_x.

Heterogeneous Processes

Heterogeneous reactions are important in the partitioning of the nitrogen and halogen families. These same reactions are important sources of HO_x in the lower stratosphere where aerosol concentrations are significant. The hydrolysis of N₂O₅ on sulfuric acid aerosols is a major source of HNO₃ and HO_x in the lower stratosphere:

The first step in this sequence is significant only at night because NO₃ is easily photolyzed during the day. Thus, this sequence is not important in the high-latitude summer when continuous sunlit conditions occur. An alternate pathway for the removal of HNO₃ in reaction [19] is reaction with OH, discussed in the next section. This pathway removes HO_x so that the yield from the hydrolysis of N₂O₅ is less than 2HO_x.

In the winter and early spring polar vortex when ClO and aerosol concentrations are high, heterogeneous reactions of ClONO₂ are the dominant source of HNO₃. The hydrolysis of ClONO₂ can be a particularly strong source of HO_x:

The heterogeneous reaction [22] is strongly temperature-dependent, proceeding fastest at low temperatures (190–200 K). As in the case of N₂O₅ hydrolysis, the reaction of OH with HNO₃ competes with [19] to reduce the yield of this sequence. In addition, the heterogeneous reaction:

competes with reaction [23] and to further reduce the yield of this sequence. When ClONO₂ is absent, as in the polar winter lower stratosphere, reaction [25] can be a net sink of HO_x. The analogous hydrolysis of BrONO₂ is only weakly temperature-dependent, and it is only a small source throughout the lower stratosphere. This reaction produces a distinct increase in HO_x when HOBr produced is photolyzed at daybreak.

Sinks

The removal of HO_x in the stratosphere consists entirely of reactions that convert HO_x to H₂O. The numerous pathways involving NO_y and HO_x intermediates are shown in Figure 1. Unlike the nitrogen and halogen radical families, HO_x radicals are not sequestered in reservoirs. This is because these potential reservoirs (HNO₃ and HNO₄) react rapidly with OH, serving as sinks instead.

The primary removal mechanism for HO_x in the lower and middle stratosphere is the reaction of OH with NO₂, followed by reaction with HNO₃:

The similar sequence that produces and removes HNO₄ also removes HO_x:

The HNO₃ and HNO₄ sequences are most important in the lower stratosphere where the concentrations of HNO₃ and HNO₄ are high. The first-order loss rates of the removal sequences are shown in Figure 3. When concentrations of ClO are elevated, the reaction

is a significant sink of HO_x. Because concentrations of HCl are usually low when ClO concentrations are high, the reaction of OH with HCl [15] that completes the conversion of HO_x to H₂O is not significant.

Figure 3 Typical mid-latitude first-order loss rates determined from profiles of the sinks of HO_x are shown versus altitude. The first-order loss rates, e.g. $k_{\text{OH}+\text{HNO}_3}[\text{HNO}_3]$, are the independent variables that control the removal of HO_x.

When the concentrations of HO_x are large the self-reaction of HO_x becomes significant:

In the mid to upper stratosphere reaction [32] is the dominant sink of HO_x. In this region of the stratosphere HO_x photochemistry is greatly simplified. Concentrations of HO_x are determined nearly entirely by production from H₂O and removal via the self-reaction.

The most significant heterogeneous removal mechanism of HO_x is the hydrolysis of N₂O₅:

This reaction is important only in the lower stratosphere where aerosol concentrations are high. As mentioned in the previous section, an alternate pathway to reaction [27] is the photolysis of HNO₃[19], so that the occurrence of [18] leads to the removal of less than 2HO_x. The analogous removal mechanisms involving ClONO₂ and BrONO₂ are less significant because the reactions of OH with HOCl and HOBr are too slow to compete with the photolysis of these species.

Secondary Sources and Sinks

The production and loss mechanisms shown in Figure 1 are portrayed as part of a one-way flux from the primary sources (H₂, H₂O, and CH₄) through HO_x and back into H₂O. On average this flux is balanced, but there are certain situations

when other pathways are significant. These processes are part of null sequences. For example, the formation followed by photolytic destruction of HNO₄ is

This is a net null for HO_x averaged over a 24-hour diurnal cycle. However at any given instant within the diurnal cycle these reactions are not required to balance. In particular, at sunrise and sunset HNO₄ is not in steady state, i.e. the rate of [29] does not balance [30] and [33]. Under these twilight conditions, this sequence can be a source (sunrise) or a sink (sunset). Other null cycles that can be instantaneous sources or sinks of HO_x include the formation and photolysis of HONO, HOCl, HOBr, and H₂O₂. Conceptually, these terms should be considered secondary processes. That is, they do not influence the interpretation of the 24-hour average abundance of HO_x versus altitude or latitude, but they are significant in model calculations that attempt to reproduce HO_x at twilight conditions.

Diurnal Change

The production of HO_x is tied to the flux of ultraviolet (UV) radiation that drives the photolysis reactions and initiates the production sequences. This UV flux, which is strongly attenuated by O₃, depends on the O₃ slant column (the amount of O₃ between an air parcel and the Sun). During a diurnal cycle, this slant column changes with the angle of the Sun, resulting in large changes in UV flux and photolysis rates. The resulting change in the production rate of HO_x for conditions typical of the mid-latitude lower stratosphere is shown in Figure 4. The sharp increase in the production rate indicates the strong

Figure 4 The production rate of HO_x is shown for a typical day in the mid-latitude lower stratosphere. The solar zenith angle is the angle between the Sun and the zenith (directly overhead). The sequences that oxidize CH₄ and the hydrolysis reactions are grouped together.

dependence on UV flux, hence solar zenith angle. The relative strengths of the sources and sinks of HO_x also depend on solar flux. For example, the oxidation of CH₄ is faster than that of H₂O at the highest solar zenith angles. This is because the oxidation of CH₄ can be initiated by OH and Cl atoms that are produced more easily than O(¹D) at twilight conditions.

HO_x Cycling

The relative concentration of H, OH, and HO₂ is controlled by fast cycling reactions that do not produce or remove HO_x. H is converted to HO₂ via the extremely fast reaction with O₂.

This reaction is significantly faster than the reactions that produce H (i.e. [9] and [16]), so that concentrations of H are negligible compared to the OH and HO₂. Because the conversion of H is so fast, H is often neglected and the production of H is considered equivalent to the production of HO₂.

The relative concentration of OH and HO₂ is controlled by reactions that interconvert OH and HO₂. The primary conversion mechanism in the lower and middle stratosphere is

This reaction sequence is a net loss for ozone, and accounts for a large fraction of the total ozone removal rate in the lower stratosphere. In this sequence, the rate constant for reaction [35] is much larger than that of reaction [36], so that concentrations of HO₂ are almost always greater than OH in the lower to mid stratosphere.

An important pathway for the conversion of HO₂ → OH is part of a null cycle:

This and the prior sequence illustrate the interaction between HO_x and NO_x on ozone loss rates. Reaction [36] removes O₃ and reaction [37] leads to the production of O₃. The relative rate of [36] compared with [37] determines the net O₃ removal rate following reaction [35].

The relative abundance of OH and HO₂ is proportional to the concentrations of the species and rate constants that interconvert OH and HO₂. In the mid-latitude lower to mid stratosphere, where reactions [35], [36] and [37] dominate the interconversion rate, the ratio HO₂/OH is controlled by O₃, NO, and the rate constants for these reactions. Figure 5 shows how the ratio HO₂/OH responds to the changes in O₃ and NO. At a fixed amount of NO, an increase in O₃ leads to greater

Figure 5 The ratio of HO₂/OH is controlled by NO antrun and O₃ in the mid-latitude lower stratosphere. The predicted ratio is shown versus NO for O₃ = 0.5 and 2.5 ppm.

HO₂/OH because the rate constant for reaction [35] is roughly 15 times faster than that of reaction [36]. At the limit of very high concentrations of O₃ (or low NO) the ratio of HO₂/OH is determined by the ratio of the rate constants for reactions [35] and [36], i.e. HO₂/OH $\sim k_{35}/k_{36}$. For a fixed amount of O₃, increases in NO lead to decreases in HO₂ because reaction [37] converts HO₂. At some limit of very high NO (or low O₃), HO₂/OH would approach zero.

When the concentrations of ClO are high, such as the wintertime polar vortex, the reaction with ClO controls the balance between OH and HO₂:

The analogous sequence involving BrO also contributes to the interconversion of OH and HO₂ and to the removal of O₃.

These sequences are almost always rate limited by reaction [41] and the analogous reaction of HO₂ with BrO.

In the upper stratosphere, the reactions with O atoms become important:

Above ~ 40 km this sequence dominates the conversion of OH and HO₂. The rate constant of reaction [43] is roughly twice as large as that for reaction [42], so that concentrations of OH are greater than [HO₂] in the highest part of the stratosphere.

The OH-initiated oxidation of CH₄, reactions [12] followed by [4], [5], [6], [7], [8], [9] and [10], converts OH to HO₂. In addition, the subsequent oxidation of CO converts OH $\rightarrow$ H, via

These reactions are important only in the lowest part of the stratosphere near the tropopause region, where they might account for a few percent of the total OH $\rightarrow$ HO₂ conversion rate.

Hydrogen Budget

Introduction

The principal components of the hydrogen budget of the stratosphere are water vapor, H_2O (mixing ratio between 3 and 4 parts per million by volume, ppmv, in the lower stratosphere), methane, CH_4 (about 1.7 ppmv), and molecular hydrogen, H_2 (about 0.5 ppmv). The first two of these are greenhouse gases, with strong absorption bands in the infrared, making their concentration and evolution of interest in studies of the balance of climate, and how this might change with time. The hydrogen free radicals such as the hydroxyl radical OH, HO_2 , and atomic hydrogen, H, are present in much lower concentrations (mixing ratios of order 10^{-11} at 30 km), but are highly reactive, and are consequently of particular importance in atmospheric chemistry. Since this article is concerned with the budget of hydrogen in the stratosphere, we shall be concerned primarily with the three species that dominate the mass: the trace radicals will only be considered in so far as they enter into reactions which determine the concentrations of the three major constituents.

Because of the importance to radiative energy exchange and chemistry, a wide range of studies of both the major and minor hydrogen-bearing species have been undertaken over the years. In what follows, we shall review the state of knowledge on the concentrations, budget, and variability of the three principal hydrogen species H_2O , CH_4 , and H_2 .

Supply of Hydrogen Species to the Stratosphere

Water vapor is continuously supplied to the stratosphere from the ocean surface, via the troposphere. While concentrations in the troposphere are high, sometimes approaching saturation near the surface, the Brewer–Dobson circulation transports air upward over the tropics, and through the tropical tropopause, which is characteristically very cold and high. This causes the ‘freeze-out’ of water by the tropopause cold trap, with the consequence that the air moving into the stratosphere is extremely dry (mixing ratios of order a few parts in 10^{-6} (see **Stratospheric Chemistry Topics: Stratospheric Water Vapor**).

In the stratosphere, oxidation of both methane and H_2 takes place, adding to the concentration of water vapor, but simultaneously H_2 can be produced by oxidation of formaldehyde, CH_2O , which itself is derived from CH_4 . The overall net effect is to cause water vapor to increase with height, mainly at the expense of methane, which decreases in mixing ratio, while molecular hydrogen stays roughly constant in mixing ratio with height (since reactions which both add and delete H_2 occur with similar rates). Later we will examine some data for H_2O and CH_4 from both a satellite and a balloon experiment, which indicate that the sum of total hydrogen, which may be expressed as $\psi = 2 \times \text{CH}_4 + \text{H}_2\text{O} + \text{H}_2$, is, as far as can be measured, constant with height through most of the stratosphere.

Loss of Hydrogen Species from the Stratosphere

There are three principal mechanisms by which hydrogen species are lost from the stratosphere:

1. by being part of the overall global circulation of descending air at mid to high latitudes;
2. by loss, particularly of the lightest component, molecular hydrogen, from the top of the the atmosphere to space;
3. by removal of ice where condensation occurs and ice particles may be removed by movement into the troposphere and subsequent ice sublimation or ice melting and liquid evaporation: this can happen, for example, at the top of cumulonimbus clouds once they begin to decay, or in the Antarctic polar vortex, where extremely low temperatures and sinking motion prevail.

Photochemistry of Stratospheric Hydrogen

Since original work in 1950 by two major figures in atmospheric chemistry and aeronomy, David Bates and Marcel Nicolet, the photochemistry of the hydrogen family has been treated many times. A valuable treatment is to be found in the book by Brasseur and Solomon (see under [Further Reading](#)). The three principal components, H_2O , CH_4 , and H_2 all enter the stratosphere from the troposphere below, as part of the general circulation of the atmosphere. In the troposphere, water vapor derives, of course, ultimately from the large reservoir in the oceans; methane comes from anaerobic processes, and molecular hydrogen is thought to be produced from cars and biomass burning, as well as from natural sources at the surface. The approximate mean values of the mixing ratios of the three as they enter the stratosphere are:

- H_2O : $\sim 3\text{--}4.2$ ppmv
- CH_4 : ~ 1.7 ppmv
- H_2 : ~ 0.5 ppmv

There has been some controversy over the so-called ‘mean entry level’ mixing ratio for water vapor, which will be discussed further below (under **Issues**).

Once the source molecules are in the stratosphere, they are carried by the circulation to higher altitudes and latitudes. In the mid-stratosphere, the methyl radical, CH_3 , is formed by oxidation processes ([I], [II], and [III] below) and then may be converted to formaldehyde, CH_2O , by schemes [IV], [V], and [VI], in the presence of chlorine and nitrogen oxides.

Note that because of the distributions of OH, O, and Cl with height, these reactions are more effective in the middle and upper stratosphere than they are nearer the tropopause. This means that little methane is converted to water vapor or molecular hydrogen in the lower stratosphere. We will consider this further below.

The formaldehyde so formed may be photolysed, or may react with OH, as in reactions [VII], [VIII] and [IX] below.

The formaldehyde produced eventually forms H_2 and H_2O , and so the sequence from methane to water vapor (and to molecular hydrogen) is established. Also, if HO_x , HCl or HCO is produced from CH_4 , it is quickly converted to H_2O , much faster than it is produced from the methane, so that these particular processes are also essentially a means of producing H_2 and H_2O from CH_4 .

Observations of Hydrogen-Containing Constituents in the Stratosphere

Satellite Observations of H_2O and CH_4

The near-global perspective offered by satellites has been used in the study of the total hydrogen budget of the stratosphere. Not only are satellite instruments capable of near-global observations, but they are also, in principle, capable of making measurements of many atmospheric constituents simultaneously, and of the way they move around. In fact, water vapor and methane, being polyatomic molecules, have active infrared spectra that provide a mechanism for remote measurement of concentrations from space, either by measurement of thermal

emission or by solar absorption at the frequencies of the relevant vibration-rotation bands. Molecular hydrogen does not, however exhibit an allowed infrared spectrum, and has not yet been measured from space.

To date, three satellite projects have provided sufficient data to make a test of the hydrogen budget possible. These are the Nimbus 7 and the Upper Atmosphere Research Satellite projects, and the ATMOS Space Shuttle instrument, all from NASA in the USA (a useful web page listed under Further Reading will allow the viewer to investigate the details of past, present, and future NASA satellite missions). On Nimbus 7, launched in 1978, the Limb Infrared Monitor of the Stratosphere, LIMS, provided first infrared measurements of water vapor, while the Stratospheric and Mesospheric Sounder, SAMS, made measurements of methane. On UARS, the Halogen Occultation Experiment, HALOE, produced a decade of measurements of both water vapor and methane, simultaneously and precisely bore-sighted (i.e., colocated), which have provided copious quantities of data with which to test theory. Also, the ATMOS experiment, a high-resolution solar tracking Fourier transform spectrometer, has been flown on a number of Space Shuttle missions, and has provided complete spectral coverage in the infrared from about 3 to 16 microns, at high spectral resolution.

Each of these experiments has been used to study the distribution throughout the stratosphere of H_2O and CH_4 , and the ratio of the changes of mixing ratio of these two constituents with height, $R = \Delta\text{H}_2\text{O}/\Delta\text{CH}_4$ is a parameter which can provide a useful test of photochemical and dynamical processes that might determine the hydrogen budget of the stratosphere, as we will discuss further below. Values in the range $R = 1.5$ to -2.0 have been found.

The sum of 'total hydrogen' mixing ratio, $\psi = 2 \times \text{CH}_4 + \text{H}_2\text{O} + \text{H}_2$, has also been examined using these satellite data, or at least that part of ψ that can be measured, i.e., $\psi^* = 2 \times \text{CH}_4 + \text{H}_2\text{O}$, (so that $\psi = \psi^* + \text{H}_2$). It has usually been assumed in such studies that the mixing ratio of H_2 is constant at 0.5 ppmv. Figure 1 shows a result for ψ^* obtained from HALOE data, for the stratosphere and mesosphere above 10 hPa. This and other work (see later) indicate that this parameter is, indeed rather constant in the stratosphere, and took values in the 1990s in the range 6.0 to 7.5 ppmv, though there does

Figure 1 Height-latitude cross section of HALOE measurements of $\psi^* = 2 \times \text{CH}_4 + \text{H}_2\text{O}$, a proxy measure of total hydrogen. Units are ppmv.

seem to be a significant trend with time, according to the SPARC report on upper-tropospheric and stratospheric water vapor (see [Further Reading](#)). The value of ψ^* starts to fall significantly from a constant value above about 0.1 hPa, where rapid production of H_2 in preference to H_2O takes over. Work by the author of this article and his colleagues has shown that, on the assumptions that the total hydrogen budget is constant, and that water vapor, methane, and molecular hydrogen are the only significant components, such measurements of ψ^* may be used to derive the distribution of H_2 , particularly in the mesosphere, where it varies significantly (see [Further Reading](#)).

Aircraft and Balloon Measurements of H_2O , CH_4 and H_2

Very many observations of water vapor have been made from balloon and aircraft platforms, far too many to review here (see the SPARC assessment listed in [Further Reading](#)). Fewer, though still many, measurements have been reported of CH_4 , and still fewer of H_2 . Those measurements in which all three species have been measured together are very few! However, because of the near-constancy of the H_2 mixing ratio in the stratosphere, measurements of just water vapor and methane have proven valuable. The advantage of local measurements over satellite measurements is, of course, that they are sensitive to smaller spatial and time scales than are satellites, so that more detailed processes may be studied. Also, many of the sensors used on aircraft and balloons, especially some of the *in-situ* sampling sensors, are capable of higher relative and absolute accuracy than are satellite sensors. One example of the use of aircraft measurements of H_2O and CH_4 is shown in [Figure 2](#). This shows scatter plots for four different flights of

an aircraft at between 17 and 20 km, in the latitude range $15\text{--}40^\circ\text{N}$, in 1993. Water vapor was measured using a photo-fragment fluorescence sensor, methane by a tunable diode laser instrument. Both measurements are local. The data are compared with a line obtained by linearly fitting the data from all four flights, which has a gradient of $m = \Delta\text{H}_2\text{O}/\Delta\text{CH}_4 = -1.94 \pm 0.27$. This is close to the value of $R = -2.0$ expected if oxidation of methane goes completely to water vapor, and if the production and loss of molecular hydrogen is in balance. This will be discussed further below.

Other balloon and aircraft instruments have included infrared sensors, cryogenic trapping followed by laboratory analysis, gas chromatography, mass spectrometry, resonance fluorescence techniques, and frost-point hygrometry.

Some Issues about the Hydrogen Budget of the Stratosphere

Entry-Level Mixing Ratio of Water Vapor

There has been some controversy over the so-called mean 'entry level' of water vapor. Values based on Nimbus 7 data of 2.7 and 3.25 ppmv have been reported, while a value of 4.2 ± 0.5 ppmv has been reported from aircraft data. However, the picture is confused by the fact that the value may actually have changed with time (reports of increases of about 1% year $^{-1}$ have been published, i.e. about 10% decade $^{-1}$, a very significant change), and because only rather limited measurements have been reported near the tropopause. What is beyond disagreement now is that such a global mean value for the entry-level water vapor is merely an average over quite a range, probably from as

Figure 2 Airborne measurements (17–20 km altitude, $15\text{--}40^\circ\text{N}$) of H_2O and CH_4 made in 1993. The results of four different flights are shown, and the solid line is the result of a straight-line fit to all the data.

low as 2 ppmv to as high as 7 ppmv in different regions: moreover, there are probably a number of different processes that control the transport of water vapor in particular from the troposphere to the stratosphere (see **Stratospheric Chemistry Topics: Stratospheric Water Vapor**), so that the globally averaged view cannot resolve these important individual processes.

The Conversion of Methane to Water Vapor

An important question is that of the ratio of $R = \Delta\text{H}_2\text{O}/\Delta\text{CH}_4$, i.e. the increase in water vapor with respect to the decrease in methane with height. It is important in part because it is a ratio we may hope to test from observations. Is this ratio $R = -2.0$, which would imply that all the hydrogen in the methane, including that converted into intermediate compounds like CH_3 and CH_2O , has been converted to water vapor, and also that the H_2 mixing ratio has not changed significantly, at different heights? In other words, a value of $R = 2.0$ reflects a balance between large production and loss rates for molecular hydrogen. Reaction [VII] above is the principal source of additional H_2 in the stratosphere. However, H_2 can also be destroyed in the stratosphere by a number of reactions with OH , $\text{O}(^1\text{D})$, and Cl . The reaction rates for these are similar to those for reactions [I] and [III]. It is thought that the balance of these formation and destruction reactions for H_2 is such that the H_2 mixing ratio does not change much with height, at least from the tropopause to 40 or 50 km, which is the domain of our concerns here.

Thus, the ratio $R = -2.0$ in those regions where the oxidation of methane is rapid: it is less than $R = -2.0$ (as low as $R = -1.6$ has been suggested) in the lower stratosphere, but this is where methane oxidation is much slower, so that the precise value of the ratio is not so important. If, in addition, as seems likely, the H_2 profile is constant with height because production and loss mechanisms are roughly in balance, then in practice we would expect $R = -2.0$ to hold virtually everywhere where significant conversion from CH_4 to H_2O occurs. There appears to have been some disagreement in the literature about the value of R , but this has arisen largely over a misunderstanding of the relative insignificance of methane oxidation near the tropopause, where the ratio is formally less than 2.0, but where the effect on the measured profiles is small.

The Total Hydrogen Content of the Stratosphere

Finally, in this section, we ask what is the total amount of hydrogen in the stratosphere? Ignoring the minor species such as CH_2O , OH , and so on, we address the parameter $\psi = 2 \times \text{CH}_4 + \text{H}_2\text{O} + \text{H}_2$, which on the basis of current theory should be constant, unless some unknown significant sources or sinks exist. Estimates of this quantity based on observations vary from ~ 6.5 to ~ 7.0 ppmv from satellite observations from the Nimbus 7 (1979) and the ATMOS experiments (early 1980s), to 8.1 ± 0.6 ppmv from aircraft measurements between 15° and 40° N, made in 1993. These

observations were made at different epochs, and since there is known to have been a long-term upward trend in tropospheric methane, and an upward trend in stratospheric water vapor (of about $1\% \text{ year}^{-1}$) between about 1980 and the present, it is possible that these differences may be due to real changes. However, the uncertainties due both to experimental error and to variability and different sampling are probably also large enough to account for these differences. For the present we must adopt a value of $\psi = 2 \times \text{CH}_4 + \text{H}_2\text{O} + \text{H}_2$ in the range 6.5 to 8.0 ppmv. More accurate measurements are needed to distinguish a real change of the hydrogen budget.

Reactive Nitrogen (NO_x and NO_y)

Y Kondo, The University of Tokyo, Tokyo, Japan

© 2003 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, volume 5, pp 2193-2202, © 2003, Elsevier Ltd.

Introduction

Reactive nitrogen (NO_y) plays important roles in controlling the abundance of stratospheric ozone. In this article, sources and sinks of NO_y are first described, together with the resulting NO_y distributions. Then, the role of NO_x, which is the most reactive form of NO_y, is explained. NO_x destroys catalytically stratospheric ozone and couples with other radical mechanisms. Photochemical processes controlling the relative abundance of component species of NO_y determine the NO_x abundance. The importance of heterogeneous reactions on sulfate aerosol is described in comparison with gas phase chemistry, typical for midlatitudes. In polar regions, sunlit conditions are very different from those at midlatitudes both in winter and summer. Behaviors of NO_x and NO_y under these extreme conditions are also explained.

NO_y

Sources and Sinks

Reactive nitrogen in the stratosphere is comprised of several component species: NO (nitric oxide), NO₂ (nitrogen dioxide), NO₃ (nitrogen trioxide), N₂O₅ (dinitrogen pentoxide), HNO₃ (nitric acid), HO₂NO₂ (peroxynitric acid), ClONO₂ (chlorine nitrate), and BrONO₂ (bromine nitrate). The sum of these species is defined as total reactive nitrogen NO_y. Namely, NO_y = NO + NO₂ + NO₃ + 2N₂O₅ + HNO₃ + HO₂NO₂ + ClONO₂ + BrONO₂. The reactions among NO_y component species do not lead to a net change in NO_y abundance.

N₂O, which is produced by bacteria in soil and released into the atmosphere, is the primary source of stratospheric NO_y. Since N₂O is very stable in the troposphere, it is transported into the stratosphere, mainly through the tropical tropopause. In the 1990s, the tropospheric concentration of N₂O was about 310 ppbv and increased at about 0.25% y⁻¹ over the 1978–96 period, due to imbalance between the global sources and sinks of N₂O. The stratosphere is a net photochemical source of NO_y and a net photochemical sink of N₂O. About 90 percent of the total loss of N₂O in the stratosphere occurs via its photolysis by ultraviolet radiation yielding N₂ and excited atomic oxygen (O(¹D)), which does not lead to NO production.

Reactions with O(¹D)) are responsible for 10% loss of N₂O.

where O(¹D)) is produced primarily by the photolysis of ozone at λ < 325. Reactions [R1], [R2a] and [R2b] occur in the middle

and upper stratosphere (at 35–45 km), mainly in the tropics where the intensity of the solar ultraviolet radiation is greatest, as shown in Figure 1.

NO_y is produced primarily via reaction [R2b]. Downward transport from the mesosphere and thermosphere, where NO is produced by solar radiation and auroral ionization, can provide an additional NO_y input to the upper stratosphere. Production of NO by lightning associated with upward transport through the tropical tropopause may be an additional NO_y source in the lower stratosphere at low latitudes, although its magnitude is poorly understood. Supersonic aircraft flying at much higher altitudes than subsonic aircraft injects NO molecules directly into the stratosphere. However, NO emissions from the currently operational Concorde are much smaller than the natural sources. There is also some emission, directly into the stratosphere, by long haul subsonic passenger aircraft, especially on flights routed over high latitudes. The net loss of NO_y occurs in the upper stratosphere and lower mesosphere, where NO is reduced into N₂ via the following reaction:

N is produced by the photolysis of NO by ultraviolet radiation. NO_y is also lost through transport of NO_y down to the troposphere where HNO₃ dissolves in water droplets and is removed from the atmosphere by precipitation.

Distribution of NO_y

Remote spectroscopic measurements by the Atmospheric Trace Molecule Spectroscopy (ATMOS) and Mk IV instruments from the Jet Propulsion Laboratory on board the space

Figure 1 Contours of the local instantaneous value at noon of the net production rate of NO_y (NO_y (production–loss)), in units of 10^{–8} ppbv s^{–1}. The rates depend on the abundance of N₂O, O₃, and other species, rate coefficients of reactions [R1], [R2a], [R2b] and [R3], and solar radiation field. Reproduced with permission from Fahey et al. (1990).

shuttle and balloons, in situ measurements on board the NASA ER-2 aircraft, and balloon experiments, in addition to many other measurements, have provided extensive data on the distributions of NO_y species, together with N₂O. NO_y mixing ratios obtained by these measurements increase with altitude from the tropopause up to about 35 km, where values peak at about 18 ppbv (parts per billion by volume) at midlatitudes as shown in Figure 2. This increase is due to an increase in the NO_y production via reaction [R2b] and to NO_y loss through the tropopause. In contrast, N₂O mixing ratios decrease with altitude due to reactions [R1], [R2a] and [R2b] as shown in Figure 2. The NO_y mixing ratio decreases with altitude above 35 km due to NO_y loss by reaction [R3] and a decrease in the NO_y production rate at low N₂O mixing ratios. In the lower stratosphere, reaction [R3] is very slow and the lifetime of NO_y defined by this loss process is longer than 10 years.

Given the increase (decrease) of the NO_y (N₂O) mixing ratios with altitude up to 35 km, NO_y is anticorrelated with N₂O for N₂O values larger than 120 ppbv, as shown in Figure 3 and Figure 4. The relationship between NO_y and N₂O obtained by measurements on board the ER-2 in the lower stratosphere is expressed as

$$[\text{NO}_y] - [\text{NO}_y]_0 = 0.07([\text{N}_2\text{O}]_0 - [\text{N}_2\text{O}]) \quad [1]$$

Here [NO_y] and [N₂O] are the mixing ratios of NO_y and N₂O in ppbv. [NO_y]₀ and [N₂O]₀ are values at the tropical tropopause, which are 0.25 and 310 ppbv, respectively. This relationship indicates that the increase in NO_y is proportional to the decrease in N₂O with a constant slope of −0.07. Namely, 3.5% of N₂O molecules lost via reactions [R1], [R2a], [R2b] and [R3] are converted to NO_y. In contrast, the NO_y mixing ratio

Figure 2 Profiles of NO_y and N₂O observed by ATMOS at 39–49° N in November 1994, Mk IV at 35° N in September 1993, and in situ balloon-borne measurements at 44° N in October 1994 at northern midlatitudes.

Figure 3 Correlation between NO_y and N₂O. The data used are the same as shown in Figure 2. In addition, the data obtained by the ER-2 measurements at 30–40° N in February and November 1994 are also shown.

Figure 4 NO_y and N₂O mixing ratios obtained around 20 km from the north-bound leg of the ER-2 flight on 12 January 1989 in the lower Arctic stratosphere. Reproduced with permission from Fahey et al. (1990).

decreases along with the decrease in the N₂O mixing ratio above 35 km where the N₂O values are lower than 40 ppbv, leading to a positive correlation between NO_y and N₂O as shown in Figure 3.

Due to its long lifetime, NO_y produced mainly in the tropical upper stratosphere is transported to higher latitudes and lower altitudes. This large-scale transport process is known as the Brewer–Dobson circulation. All long-lived trace gases, including ozone, N₂O, and CH₄, are subject to this transport. As a consequence, the NO_y (N₂O) mixing ratios in the lower stratosphere are higher (lower) at higher latitudes, as can be seen from Figure 4. In general, compact correlations have been observed between long-lived species whose local photochemical lifetimes exceed the time scales for atmospheric transport as predicted theoretically. The NO_y–N₂O correlation shown in Figure 3 and Figure 4 is consistently compact, especially in the lower stratosphere, where the N₂O mixing ratios are higher than 120 ppbv. This correlation has proved to be very useful in predicting NO_y abundances from observed N₂O mixing ratios as described below.

Gas Phase Chemistry

Role of NO_x

A scheme showing important reactions controlling the level of each reactive nitrogen species is shown in Figure 5. Altitude profiles of NO_y species observed by Mk IV at 35° N in September 1993 are shown in Figure 6. The time constants for the photolysis of NO_y species for local noon at 44° N in October are shown in Figure 7). NO and NO₂ are the most reactive among NO_y species. NO is oxidized to NO₂ by ozone and NO₂ is photolyzed by visible sunlight to reform NO and atomic oxygen (O).

NO and NO₂ are often treated as a sum, defined as NO_x, because the time required for the exchange between NO and NO₂ during daytime is about 1 min (Figure 7).

Figure 5 Schematic of the reaction pathways between the principal NO_y component species in the lower stratosphere. Photolysis reactions are indicated by $h\nu$. 'Sulfate aerosol' denotes heterogeneous reactions on sulfuric acid aerosol particles. Reproduced with permission from Gao et al. (1999).

NO_x plays important roles in controlling stratospheric ozone. First, NO_x destroys ozone catalytically via the following reactions:

Figure 6 Observed (symbols) and calculated (lines) profiles of NO_y species, as indicated, for sunset at 35° N on 25 September 1993. Sunrise profiles for N₂O₅ are also shown. The NO_y profile represents the sum of nitrogen oxides measured by Mk IV and was used to constrain the model. The model calculation used JPL 2000 kinetic data. Reproduced with permission from Sen et al. (1998), modified for using updated model calculations by RJ Salawitch.

Figure 7 Time constant of the NO_y species due to the photolysis between 15 and 30 km altitude, for noon at 44° N on 12 October. Courtesy of MY Danilin.

The cycle is catalytic since NO_x is conserved: NO and NO₂ are simply interchanged. Reaction [R6] is rate determining for the catalytic cycle since reaction [R4] proceeds faster than reaction [R6] in the stratosphere. The ozone loss rate is therefore proportional to the product of the NO₂ and O concentrations ([NO₂][O]). Reactions analogous to [R4] and [R6] also represent catalytic ozone loss cycles by reactive hydrogen (HO_x), chlorine (ClO_x), and bromine (BrO_x) species if NO is replaced with OH, Cl, and Br, respectively. Similar to the NO_x catalytic cycle, the rate-determining reaction for the HO_x, ClO_x, and BrO_x cycles are

where X is OH, Cl, or Br, respectively. Ozone loss rates are therefore proportional to the product of the concentrations of XO and O ([XO][O]).

Secondly, NO_x buffers the ozone loss by HO_x, ClO_x, and BrO_x by converting OH, ClO, and BrO into HNO₃, ClONO₂, and BrONO₂, which do not destroy the ozone directly, via the following reactions:

Here, the third body M represents the major atmospheric molecules N₂ and O₂. Hence, the relative importance of catalytic loss cycles of ozone by HO_x, ClO_x, and BrO_x is strongly dependent upon the NO_x abundance.

NO_x buffers HO_x and ClO_x catalytic cycles also by the following interchange reactions:

Reactions [R11] and [R12] decrease the HO₂ and ClO levels, respectively, by shifting the HO₂/OH and ClO/Cl ratios. The reductions in HO₂ and ClO lead to decreases in ozone loss rates, which are proportional to [HO₂][O] and [ClO][O], as mentioned above. On the other hand, these reactions increase the NO₂/NO ratio, enhancing the ozone loss rate by the NO_x cycle. Profiles of the ozone loss rates by the NO_x, HO_x, ClO_x, and BrO_x cycles at 35° N in September are shown in Figure 8.

Oxidation of NO_x

NO_x levels are also controlled by chemical processes that lead to the production and loss of NO_x as detailed below. NO_x produced by reaction ([R2b]) is converted to higher oxides of nitrogen (N₂O₅, HNO₃, HO₂NO₂, ClONO₂, BrONO₂). Since these NO_y species do not react directly with ozone but produce NO_y by photolysis and reactions with OH, they are called reservoir NO_y species. N₂O₅ is produced through the following reactions:

Figure 8 Odd oxygen sinks at 35° N on 25 September 1993. The fractional contribution of the dominant sinks and the diurnally averaged loss rate of odd nitrogen, computed using constraints imposed by the MK IV data. Losses due to each catalytic cycle are indicated as NO_x, HO_x, ClO_x, and BrO_x. O₃ + O denotes loss by recombination reaction of odd oxygen. Heterogeneous reactions included in the model calculations increase the contributions from HO_x, ClO_x, and BrO_x. Courtesy of RJ Salawitch and B Sen.

Reaction [R13] is rate determining for the formation of N₂O₅, which occurs only during nighttime since NO₃ is photolyzed within a few seconds by visible radiation ($\lambda < 670$) during daytime (Figure 7).

Other reservoir NO_y species are produced via reactions [R8], [R9] and [R10] and the following reaction:

Conversely, NO_x is produced by decomposition of reservoir species, such as

Here the photolysis wavelength thresholds are given for absorption cross-section limits of about $1 \times 10^{-21} \text{ cm}^2$.

Typical lifetimes of N₂O₅ and HNO₃ in the lower stratosphere as determined by the above decomposition processes are several hours and 1 week, respectively, for noontime

midlatitude fall conditions, as shown in Figure 7. Below 25 km, HNO₃ is the dominant NO_y species since NO_x is oxidized to form HNO₃ via the three-body reaction [R8], which proceeds faster at lower altitude (higher pressure) as shown in Figure 6. At higher altitudes, NO_x dominates among the NO_y species due to enhanced NO_x production by reactions [R17], [R18], [R19a] and [R19b]. The 2 × N₂O₅ mixing ratio at sunrise becomes comparable to NO_x in the lower stratosphere. The ClONO₂ mixing ratio shows a broad peak of about 1 ppbv centered around 25 km.

Diurnal and Seasonal Variations at Midlatitudes

NO_y species undergo temporal variations depending on their chemical lifetimes as shown in Figure 9. NO is oxidized to NO₂ within a few minutes after sunset and NO_x exists in the form of NO₂ during nighttime. Part of the NO₂ is photolyzed to produce NO soon after sunrise. Due to the formation of N₂O₅ during the nighttime and photolysis during the daytime, N₂O₅ mixing ratios reach maximum and minimum values at sunrise and sunset, respectively, as is partly shown by Mk IV observations (Figure 6). Corresponding to the diurnal variation of N₂O₅, NO_x shows a slow increase in the morning reaching a maximum value at sunset, when it starts to decrease again until sunrise. In contrast, HNO₃ does not undergo significant diurnal variation since the lifetime of HNO₃ is about a week as described above. Both N₂O₅ and HNO₃ levels respond to the seasonal variations of solar elevation and sunlit hours. The HNO₃/NO_y and N₂O₅/NO_y ratios at midlatitudes reach minimum values at summer solstice due to the largest rates of reactions [R17] and [R18]. Similarly, they reach maximum values near the winter solstice. The NO_x mixing ratio and NO_x/NO_y ratio show almost sinusoidal seasonal variations reaching maximum and minimum values at summer and winter solstices, respectively, as shown by ground-based and satellite remote sensing observations.

Heterogeneous Chemistry

Sulfate aerosol composed of liquid sulfuric acid (H₂SO₄) is ubiquitous in the lower stratosphere from the tropics to the polar regions. H₂SO₄ in the stratosphere is produced through oxidation of sulfur-containing gases transported from the troposphere mostly in the form of carbonyl sulfide (OCS). In addition to the gas phase chemistry described above, the partitioning of NO_y is also controlled by the heterogeneous reactions on sulfate aerosols listed below:

Here (g) and (a) denote species in gas phase and in aerosol, respectively.

Reaction [R23] occurs with a reaction probability of 0.1, weakly dependent on the composition of aerosols, temperature, and particle size. On the other hand, the effects of reactions [R24] and [R25] are important only at very low temperatures in high-latitude winter (temperature <210 K). Reaction [R26] is fast, but its impact on nitrogen species partitioning in the stratosphere is smaller than that due to reaction [R23] because of the smaller bromine content (~10 pptv (parts per trillion by volume)).

These reactions, especially reaction [R23], convert shorter-lived reservoir N₂O₅, ClONO₂, and BrONO₂ into longer-lived HNO₃, even at low and midlatitudes. They lengthen the time required to regenerate NO_x via reactions ([R18], [R19a], [R19b] and [R20]), resulting in an effective decrease in the NO_x levels (Figure 5). In addition, reaction [R23] oxidizes NO_x without consuming OH, resulting in a higher OH level. The higher OH abundance accelerates reaction [R8] causing further reduction in NO_x. The reduction of the NO_x/NO_y ratio in a stratospheric model due to the effect of heterogeneous reactions is shown in Figure 10.

The reduction of the NO_x level by heterogeneous reactions leads to increases in the HO_x, ClO_x, and BrO_x levels because of the slower reaction rates of reactions [R8], [R9] and [R10] at lower NO_x concentrations. The reduction of the NO_x level by heterogeneous reactions leads to increases in the HO_x, ClO_x, and BrO_x levels because of the slower reaction rates of reactions [R8], [R9] and [R10] at lower NO_x concentrations. The nonlinear dependence of ozone loss rates on HO_x, halogen (ClO_x and BrO_x), and NO_x abundances are shown in Figure 11. At the lowest NO_x levels (left dotted lines in Figure 11), ozone loss rates increase due to increased abundances of HO_x and halogen species that result from the lowering of NO_x in an air parcel. Typical values at midlatitudes (right dotted lines in Figure 11) are near the mid-range NO_x values where ozone loss rates have low sensitivity to the abundance of NO_x.

The effect of heterogeneous reactions on NO_x and ozone is enhanced by volcanic eruptions. Associated with large volcanic eruptions, significant amounts of SO₂ are injected into the stratosphere. The injected SO₂ is oxidized to H₂SO₄, which forms subsequently sulfuric acid aerosols within a short time. Mount Pinatubo in the Philippines erupted in June 1991 and

Figure 10 Vertical profiles of the NO_x/NO_y ratios (small solid circles) derived from the balloon observations made at 44°N on 12 October 1994. Bars show the total uncertainties in the NO_x and NO_y measurements. The calculated NO_x/NO_y ratios incorporating heterogeneous chemistry and gas phase chemistry only are compared. Reproduced with permission from Kondo et al. (2000), modified for using NO_x/NO_y ratio instead of NO/NO_y ratio.

Figure 11 The O_3 removal rate versus NO_x levels. Because of the coupling that exists between the radical families, the response of the total O_3 removal rate to changes in NO_x abundance is highly nonlinear. At sufficiently low NO_x levels, such as observed at midlatitudes in May 1993, the removal rates are inversely correlated with NO_x abundance.

the aerosol loading increased by up to a factor of 100 over background values. The aerosol loading remained high for a few years with a gradual decrease with time. Corresponding to this enhanced aerosol loading, significant reductions in NO_x were observed as shown in Figure 10. It should be noted that the rate of reaction [R23] at large aerosol surface area is limited by the formation rate of N_2O_5 [R13] during the nighttime. Therefore the decrease in NO_x by reaction [R23] saturates eventually at a certain surface area, depending on photochemical conditions. The reduction in NO_x caused the decrease in the ozone levels as observed by a variety of in situ and remote sensing measurements, providing evidence of the effect of heterogeneous reactions on stratospheric chemistry.

Polar NO_x and NO_y Winter

Both NO_x mixing ratios and NO_x/NO_y ratios have been observed to decrease sharply at latitudes higher than $50\text{--}60^\circ$ in winter and early spring as shown in Figure 12. This large and sharp decrease in NO_x is caused by the large reduction of sunlight in high-latitude winter, which reduces greatly the formation of NO_x from NO_y reservoir species. N_2O_5 produced in the dark stratosphere is converted effectively to HNO_3 via reaction [R23] before being photolyzed. Therefore, HNO_3 dominates among the NO_y species in high-latitude winter.

The temperature in the Antarctic and Arctic lower stratosphere decreases to as low as 190–185 K by midwinter in the absence of solar heating. Under these very low temperatures, HNO_3 co-condenses with H_2O and/or H_2SO_4 to form polar stratospheric cloud (PSC) particles. These particles provide sites for heterogeneous reactions, such as reactions [R24] and [R25], which convert unreactive inorganic chlorine species into reactive chlorine very efficiently. The reactive chlorine destroys the ozone rapidly when exposed to sunlight. In addition, a polar vortex with westerly winds forms as the high-latitude stratosphere cools each winter season. The polar vortex isolates partially high-latitude stratospheric air from midlatitude air. Extensive ozone depletion inside the vortex in early spring over the Antarctic is well known as the Ozone Hole. Similar processes occur during the cold Arctic winters, although the temperatures in the Arctic are much warmer and show larger

Figure 12 Contrast in the vertical distribution of NO_x in winter and summer. The balloon-borne in situ measurements were made at 51°N in August and December 1982. A strong reduction of NO_x occurred at 20–28 km. Reproduced with permission from Ridley et al. (1987).

Figure 13 N_2O , NO_y , and H_2O mixing ratios observed by ER-2 at 16–19 km altitude from a portion of a flight in the Antarctic and Arctic missions. The average relation between NO_y and N_2O Equatorward of the vortex boundary (dashed line) is given by eqn [1]. The shaded areas, highlighting the difference between measured NO_y and NO_y calculated from eqn [1], represent denitrification in the sampled air masses. Reproduced with permission from Fahey et al. (1990).

year-to-year variations. In this way, HNO_3 contributes to ozone destruction through the formation of PSC particles.

With the reappearance of the Sun in early spring, NO_2 is produced from HNO_3 by reactions [R16] and [R17]. NO_2 deactivates reactive chlorine and bromine by reactions [R9] and [R10]. This process decelerates effectively the ozone destruction by halogen radicals after the formation of PSCs ceases in spring when the temperature rises above the PSC formation threshold. However, spring HNO_3 levels, and therefore NO_2 levels, are often much lower than in late fall or early winter for the following reason. HNO_3 -containing PSC particles in the crystalline form sometimes grow to larger than $10\ \mu\text{m}$ in radius under continued very low temperatures in midwinter. These particles fall out of the stratosphere in a few to several days, leading to permanent removal of NO_y . This NO_y loss process, called denitrification, lowers the level of HNO_3 , resulting in a delay in the deactivation of chlorine and extending the period of ozone depletion throughout the winter and early spring.

Denitrification has been detected as deviations of the NO_y values from those anticipated from the reference NO_y – N_2O correlation observed prior to denitrification in late fall as shown in Figure 13. Equation [1] represents a good reference for N_2O higher than 120 ppbv. Extensive denitrification occurs in the Antarctic winter, when temperatures fall persistently below even the ice saturation threshold. The temperature in the Arctic in winter is somewhat higher and much more variable than in the Antarctic, as described above, resulting in less extensive denitrification. Falling PSC particles evaporate if they experience temperatures higher than the HNO_3 – H_2O condensation threshold temperature. This leads to local enhancement in NO_y over the background value as has been observed at 12–15 km in the Arctic.

Summer

During the summer, large regions of the polar stratosphere receive uninterrupted sunlight for many weeks. Under these

conditions, daily N_2O_5 production via reactions [R13] and [R14] ceases abruptly with the onset of continuous photolysis in high-latitude air masses, because NO_3 , the intermediate in its formation, is photolyzed rapidly, thereby preventing N_2O_5 formation. Depletion of N_2O_5 shuts off the hydrolysis of N_2O_5 in the heterogeneous reaction [R23]. In addition, the photolysis of HNO_3 is augmented by continuous sunlight. The NO_y family simplifies to a near ‘gas-phase-only’ system in summer air masses because the NO_x/HNO_3 ratios become primarily controlled by reactions [R8], [R16] and [R17]. Due to these conditions, the NO_x/NO_y ratios at 18–20 km observed by the ER-2 aircraft in polar summer reach as high as 0.25, which are much higher than those at lower latitudes. It is noted that gas phase models predict NO_x/NO_y ratios close to those observed in polar summer even for midlatitude near equinox (Figure 10), thereby demonstrating the importance of reaction [R23] in determining the NO_x levels in the lower stratosphere. High NO_x abundances in polar summer have also been observed by satellite and ground-based spectroscopic measurements.

The measurements by the ER-2 aircraft of related radicals have shown the predominance of the NO_x catalytic ozone loss cycle over the HO_x , ClO_x , and BrO_x cycles in polar summer under high NO_x , as can be understood by the diagram of Figure 11. Total ozone loss rates calculated using aircraft data are as high as 10–20% per month at 18–20 km at 60–90° N in June. This ozone loss rate is consistent with that observed by satellites.

Stratospheric Water Vapor

KH Rosenlof, Earth System Research Laboratory, National Oceanic and Atmospheric Administration, Boulder, CO, USA

© Published by Elsevier Ltd.

Synopsis

Stratospheric water vapor plays a significant role in the climate system. In spite of the fact that its concentration is very small, it plays key roles in radiative and chemical processes. Additionally, its distribution can be used to assess zonally averaged transport processes as well as changes in stratospheric transport that are not directly measurable but important for understanding the evolution of the stratospheric ozone layer. Key mechanisms that contribute to the control of stratospheric water vapor concentrations are stratospheric photochemistry and transport, tropical tropopause dehydration, and polar dehydration. Transport from troposphere to stratosphere at midlatitudes also appears to impact stratospheric water vapor. Although global water vapor trend determination from the historical record is difficult due to the lack of long-term continuous measurements, there are indications that the stratospheric water vapor has increased over the past 50 years, which is to be expected given that methane emissions have increased, and oxidation of methane is the major production of water vapor in the stratosphere. However, we do not fully understand the stratospheric water vapor budget and the mechanisms that control entry into the stratosphere. It is therefore difficult to predict changes expected in a future climate, and hence the study of stratospheric water vapor remains an active area of research.

Introduction

The Earth is a planet ruled by water. Water exists in all three phases (solid, liquid, and gas) at commonly observed surface and atmospheric temperatures. It is of vital importance to the planet's ecosystem, with virtually all life that we know of depending on it. What we call weather is really the process of moving water through our ecosystem.

The water vapor content of the atmosphere is high near the surface, and drops down to extremely small values in the upper reaches of the troposphere. **Figure 1** shows a plot of the water vapor profile over Boulder, Colorado (40 °N). The concentration of water vapor in this plot is shown as a relative fraction of the total mass of air at any given altitude and is plotted as 'parts per million by volume' (ppmv). What this means is only a few molecules in every million (10^6) are water molecules. **Figure 1** is on logarithmic scale, so it shows the large dynamic range of

water from the surface to the stratosphere. The range goes from several thousand ppmv mixing ratio to less than ten ppmv at the upper reaches of the balloon flight, which is well into the stratosphere.

In the stratosphere, the water vapor concentration is very small. Nevertheless, this small concentration is profoundly important. This extreme dryness was first discovered during high-altitude research flights in Canberra aircraft over the United Kingdom, beginning as long ago as 1943 and continuing for many years thereafter. With a frost point hygrometer, a mirror surface is cooled until the ambient humidity causes a frosting of the surface: knowing the temperature at which this happens, and the local air pressure allows the humidity to be calculated. Using this device, scientists from the British Meteorological Office measured frost point temperatures at the tropopause (the boundary between the troposphere and stratosphere) of 215 K, which corresponds to a mixing ratio of about 55 ppmv. At altitudes about 2 km above the local tropopause, mixing ratios of 3 ppmv were observed. This proved to be a mystery initially, because, at the time of these measurements, the stratosphere was believed to be quiescent and in radiative equilibrium.

These extremely dry values measured in the stratosphere, coupled with observations of ozone and helium, led to the postulation that the overall circulation between the troposphere and the stratosphere was upward in the tropics across the tropopause and downward at middle-to-high latitudes. This circulation transports tropical air with tropospheric qualities into the stratosphere, and at higher latitudes, transports air with stratospheric qualities back into the troposphere. The classic 1949 paper describing this is by A. W. Brewer, and the circulation, known now as the Brewer–Dobson circulation, is shown in **Figure 2**. What Brewer realized that enabled him to deduce such a circulation existed with only vertical profiles of water over England, was that water vapor mixing ratios were extremely low in the stratosphere. How much water a parcel of air holds is a strong function of its temperature history, with colder values yielding lower values of water vapor. The only place that Brewer knew that was cold enough to achieve those

Figure 1 Water vapor profile from the balloon borne NOAA frost point hygrometer. This profile was measured over Boulder, Colorado, located at 40 °N. Data taken by the Global Monitoring Division of the NOAA Earth System Research Laboratory in Boulder, CO.

Figure 2 A contour plot of zonally averaged temperatures, taken from Brewer, A., 1949. Evidence for a world circulation provided by the measurements of helium and water vapor distributions in the stratosphere. Quarterly Journal of the Royal Meteorological Society 75, 351. The line with longer dashes indicates the tropopause. The solid lines with arrows indicate the direction of the circulation.

low mixing ratios was the tropical tropopause (see zonally averaged temperatures in Figure 2). Brewer also knew that stratospheric ozone was produced in the tropics, and that G. Dobson, in a 1929 paper, had found that the column of ozone is largest at high latitudes, hence the general flow in the stratosphere had to be poleward. Brewer's extremely clever detective work using a minimum of observations led to, what we know definitively today, the mean meridional stratospheric circulation.

It is well known that water vapor is the principal greenhouse gas and plays a key role in the tropospheric and stratospheric chemistry. Throughout the atmosphere, water vapor plays both a radiative and chemical role. An increase in stratospheric water vapor will radiatively cool the lower stratosphere and also affect the frequency of occurrence of polar stratospheric clouds, thereby impacting the stratospheric ozone chemistry. Enhanced levels of stratospheric water vapor strengthen ozone loss in the presence of ozone depleting substances (ODS). Hence, a climate with increased stratospheric water vapor will have a delayed ozone recovery even while ODSs are reduced. Changes in the stratospheric water vapor also can be a significant radiative forcing for surface climate. A $\sim 10\%$ drop in stratospheric water vapor levels near the tropopause at the end of 2000 has been estimated to have contributed a radiative forcing of -0.1 W m^{-2} ; this may have slowed the amount of warming from CO_2 increases over the 2000–09 period by 25%. Decadal variations of stratospheric water vapor concentrations also likely contributed to an enhanced rate of surface warming in the 1990s (Figure 3).

It is clear that the humidity of the stratosphere is important because the amount of water vapor determines important

Figure 3 Decadal warming rates arising from well-mixed greenhouse gases and aerosols alone (black), as well as from including the stratospheric water decline after 2000 (red), and including both the stratospheric water vapor decline after 2000 and the water vapor increase in the 1980s and 1990s (cyan). The Bern intermediate complexity climate model was used for these estimates; it does not simulate internal variability from one year to another. Volcanoes were not been included in the radiative forcing. The climate sensitivity of the model used is 3°C for a doubling of atmospheric CO_2 , and the transient climate response is 1.7°C , slightly less than the mean of the range of models assessed by the Intergovernmental Panel on Climate Change (1). From Solomon, S., Rosenlof, K. H., Portmann, R., Daniel, J., Davis, S., Sanford, T., Plattner, G.-K., 2010. Contributions of stratospheric water vapor changes to decadal variations in the rate of global warming. Science 327, 1219–1223.

aspects of the planetary radiative energy balance through the strong cooling of space from water vapor. This contributes to determining the temperature of the stratosphere, which then affects the dynamical circulation of the upper atmosphere. Moreover, water vapor provides the source of the hydroxyl radical, OH, which takes part in a number of stratospheric chemical processes. Additionally, water vapor concentrations impact stratospheric temperature, which in turn can affect stratospheric chemistry through temperature dependent reaction rates. An understanding of how the distribution of water vapor is controlled, and of how this distribution might change in future, is therefore important for understanding certain aspects of climate change.

Water Vapor Observations

Because water exists in all three phases in the Earth's atmosphere, water vapor has proven difficult to measure at extremely high accuracy throughout the depth of the atmosphere. It is also difficult to determine how water vapor has changed in the industrial time period. After Brewer's pioneering measurements from aircraft, high-altitude balloons were used, and initially, these measurements indicated a much wetter stratosphere. However, it was soon realized that the balloon data were contaminated by moisture carried up by the balloon itself. A change in operating procedure, with measurements taken on descent and the inlet ahead of the instrument avoided the extraneous moisture from the balloon outgassing. Measurements taken by scientists at the Naval Research Laboratory in the United States and later from the National Oceanic and Atmospheric Administration (NOAA) showed that stratospheric humidity was indeed low, with small increases from the hygropause (level of minimum water) to 30 km in altitude. These balloon measurements, extending from the 1960s to present day, first over Washington DC and then Boulder, Colorado, form the backbone of our long-term record of stratospheric water vapor. In the recent years, regular frost point measurements have been made in the Southern Hemisphere (Lauder, New Zealand), the tropics and subtropics (San Jose, Costa Rica, and Hilo, Hawaii), and Europe (Lindenberg, Germany). Associated with various aircraft campaigns and intensive observation programs, there have been frost point balloons flown at other sites around the world. These sites include Indonesia, the Galapagos, and on ships as a part of the Japanese program known as SOWER (soundings of ozone and water in equatorial regions). Frost point balloon measurements have also been made associated with a number of aircraft campaigns and for satellite validation studies. The frost point balloon sonde will be used as a water vapor standard within the Global Climate Observing System Reference Upper Air Network.

Typically deployed on a campaign basis, there are instruments other than frost point hygrometers capable of measuring water at low stratospheric concentrations. A step up in sensitivity, which allowed measurements at much higher time and space resolution to be made, came with the invention of an alternative measurement technique using the resonance fluorescence hygrometer. This device uses the spectroscopic property of the water vapor molecule that if it is illuminated by

ultraviolet radiation from a lamp at a certain frequency, it will reemit radiation in measurable quantities and with an intensity that is proportional to the relative amount of water vapor to air molecules in the line of sight. This device has been widely deployed on aircraft and balloons around the world, and has given rise to a much more finely detailed knowledge of how water vapor is distributed around the globe. It was using this device that the 'hygropause,' a minimum in mixing ratio some 2–3 km above the local tropopause, was discovered in tropical regions. Since the first balloon borne Lyman-alpha hygrometers were flown, there have been versions built to also fly on high-altitude aircraft by several research and educational institutes around the world. The Lyman-alpha record forms a fairly long time record of water vapor measurements.

Tunable diode laser spectrometers are also used, both on aircraft and balloon, for *in situ* measurements of water vapor in both the troposphere and stratosphere. These use infrared absorption to determine water vapor concentration and there are both open and closed path versions of these instruments, flying on both balloons and aircraft. A technique newly developed for stratospheric water vapor is a chemical ionization mass spectrometer. For this instrument a portion of the sample flow passes through an ionization chamber where it is exposed to α -particle radiation. Air reacts with α -particles producing mostly O_2^+ and N_2^+ , which lead to a series of ion-molecule reactions resulting in the production of H_3O^+ ions from ambient H_2O . Ions are analyzed using a quadrupole mass spectrometer and the measured count rate of the H_3O^+ analyte ions is used to quantify ambient water vapor.

Operational radiosondes, typically using capacitive hygrometers, unfortunately are not able to measure the very low values of water vapor found in the stratosphere. So, there are limited long-term *in situ* records that can be used to look at long-term changes in stratospheric water vapor.

For a global view of the stratospheric water vapor distribution, space based techniques are essential. The first stratospheric water vapor measurements from satellite were made by the NASA Limb Infrared Monitor of the Stratosphere (LIMS) on the Nimbus 7 spacecraft launched in 1978. This device, which employed sensitive cooled detectors in space, detected emission from stratospheric water vapor from one of its infrared vibration-rotation bands (the ν_2 band centered at 6.3 μm). The intensity of this emission is proportional to the atmospheric temperature and the water vapor concentration. Knowing the temperature from separate measurements allowed the water vapor concentration to be determined globally as a function of altitude and position. This was a very exciting development, which employed the new technique of limb-sounding that increased the precision of stratospheric measurement by aiming the instrument sideways, toward the limb of the atmosphere, where the stratosphere is exposed against the cold and dark background of space. Nimbus 7 was notable for another reason: this program introduced the idea of assembling international 'Experiment' or 'Science' teams to assist in the development and scientific exploitation of the experiments onboard the satellite, a method adopted in almost all satellite experiments since.

There have been a large number of space-based water vapor instruments since LIMS. Also on Nimbus 7 was the British instrument called the stratospheric and mesospheric sounder,

which used another new technique, pressure modulation radiometry, to detect and measure water vapor (among other gases). This technique actually carried a sample of water vapor in a cell onboard, as a type of 'calibrator' of the detected infrared emissions. A Fourier transform spectrometer called ATMOS (atmospheric trace molecule spectroscopy) was flown several times on the space shuttle in the 1980s and 1990s, providing highly accurate spectral information about water vapor and many other stratospheric molecules. Long-term measurements were initiated using shorter-wavelength visible and near ultraviolet observations of water vapor absorption, using the Stratospheric Aerosol and Gas Experiment (SAGE). The Upper Atmosphere Research Satellite (UARS) launched in 1991 and operated until 2005, included the Halogen Occultation Experiment (HALOE). HALOE measured the absorption of infrared solar radiation by stratospheric water vapor, using the LIMS technique of looking through the limb of the atmosphere, in this case as the Sun rises or sets behind the atmosphere. The first Microwave Limb Sounder (MLS) also flew on UARS; it operated in the millimeter wave part of the spectrum. Currently flying on the NASA Aura satellite is another MLS; this one has operated since 2004. The Atmospheric Chemistry Experiment (ACE), a satellite mission onboard the Canadian satellite SCISAT-1 launched in 2003, includes a Fourier transform spectrometer performing measurements on several lines in the $1362\text{--}2137\text{ cm}^{-1}$ range; from these H_2O concentration profiles are retrieved up to 90 km in altitude. The Michelson Interferometer for Passive Atmospheric Sounding (MIPAS) onboard the Envisat research satellite provided stratospheric water vapor measurements from 2002 to 2012 when communications with Envisat were lost. MIPAS is a mid-infrared limb emission Fourier transform spectrometer designed for global vertical profile measurement of temperature and many atmospheric trace constituents relevant to atmospheric chemistry and climate change. ATMOS, ACE, and MIPAS are among instruments providing measurements of water vapor isotopologues, which have provided new insights on transport pathways from troposphere to stratosphere. This has not been a complete listing of remote sensors measuring stratospheric water vapor, but gives a sampling of the rich number of techniques available. There are also ground-based and balloon-based remote sensing instruments that provide water vapor measurements and have proved useful for monitoring at individual sites or for specific campaigns.

The *in situ* and remotely sensed water vapor measurements have helped us to understand much about what controls stratospheric humidity, and possible relations to tropospheric climate and stratospheric transport. Puzzles do remain, a few of which are discussed below.

Control of the Mean Distribution and Variability of Stratospheric Water Vapor

It is one of the fascinations of the study of stratospheric humidity that, while this extreme aridity and the overall mechanisms causing it have been known for more than half a century, the detailed understanding of precisely how this state is maintained remains elusive. This basic theory of the humidity of the stratosphere has survived and today forms

the basis of our understanding. However, we now realize that there are many important details that modify this model.

The key mechanisms that contribute to the control of stratospheric water vapor concentrations are stratospheric photochemistry and transport, tropical tropopause dehydration, and polar dehydration. Additionally, transport from troposphere to stratosphere at midlatitudes also appears to impact stratospheric water vapor.

Stratospheric Photochemistry

In the stratosphere, the high intensity of short-wave solar radiation means that methane and molecular hydrogen can be photolyzed, which releases active hydrogen compounds. When methane is oxidized it produces roughly two molecules of water vapor for every one molecule of methane destroyed. As a consequence, the quantity $2(\text{CH}_4) + (\text{H}_2\text{O})$ is quasi-conserved; this fact is useful for inferring motions and origins of air masses in the stratosphere. Lifetimes of both methane and molecular hydrogen are over 100 years at the tropopause, a few years at 30 km, and a few months at 40 km, owing to the increasing solar flux at short wavelength. Thus, air can be 'tagged': low values of (CH_4) and high values of (H_2O) in lower stratospheric air indicate that the air has been transported down from higher altitudes.

Tropical Tropopause Dehydration

The mechanisms responsible for stratospheric dehydration have been studied for more than 60 years; the concept was first introduced in a seminal paper by Alan Brewer, published in 1949. It is an amazing fact that, despite more than 60 years of research, we are still unsure about the precise mechanism(s) that cause the 'cold trap' phenomenon at the tropical tropopause. To first order, freeze-drying happens as air passes through the cold tropical tropopause when air cools, saturates, ice forms, and then falls out. Variations, such as an annual cycle in tropical lower stratospheric water, have been shown to be directly related to similar variations in tropical tropopause temperature; however, the zonally averaged tropical tropopause temperature is not low enough to produce the observed very low values in the stratosphere. This indicates that there are preferential longitudinal regions for the final dehydration of air entering the stratosphere, and trajectory model calculations using winds derived from data assimilation of wind and temperature fields support that conclusion. Current modeling and observational work is concentrating on teasing out the details of the microphysics involved in the final dehydration of air entering the stratosphere. Because models do not necessarily represent the physical processes involved with dehydration accurately in the tropical tropopause region, our predictions of changes in stratospheric humidity in the future are highly uncertain.

Polar Dehydration

Within the stratospheric vortices that form around each of the poles in winter, temperatures can fall to extremely low values (e.g., 180 K) and, of course, the air in the vortex is dehydrated under such conditions. In the north, the strength of the vortex, the amount of cooling within the vortex, and the consequent

degree of dehydration is not thought to be sufficient to affect the annual mean. However, in the south, the dessication is very significant and impacts the annual mean, even though it is only a seasonal effect. Below the 400 K potential temperature surface, in spring and summer, dehydration can affect midlatitudes, but the effect on the rest of the stratosphere is minimal.

Troposphere Stratosphere Exchange at Midlatitudes

In the midlatitude lower stratosphere, the extreme dryness of the stratosphere is maintained against the relatively very high humidity of the tropopause just a few kilometers away under the tropopause. At these latitudes there is not the strong vertical convection to maintain the cold trap mechanism and tropopause temperatures are warmer on average than at lower latitudes. What happens? First, the air in the stratosphere is, on the average, subsiding from higher up and so maintains an appropriate level of moisture, though there is also 'leakage' through the tropopause at midlatitudes. The most likely route is from the tropical high tropopause, along isentropes, passing through the break in the tropopause that often exists at midlatitudes (as a result of deformation of the tropopause into 'folds,' caused by various tropospheric dynamical features such as low-latitude troughs). The influence of high topography, such as the Himalayas and the Tibetan Plateau is also thought to influence isentropic flow from tropical upper troposphere into midlatitude stratosphere. There is also evidence that the summer monsoonal circulation, both for Asia and North America, result in water vapor transport into the lowermost stratosphere. Convection overshooting the tropopause may inject ice into the lower stratosphere, but that contribution has not been quantified at this point. It is clear that explaining the mean distribution of water vapor in the stratosphere involves understanding not only the global mean circulation, but also a range of detailed tropopause-level processes. A range of spatial and temporal scale processes are likely important.

Timescales

Each source of stratospheric water vapor is associated with a distinct timescale. The input of water vapor into the stratosphere by an individual air parcel in the tropics is largely a function of the lowest temperature a parcel encounters on its transit into the stratosphere, as originally noted by Brewer. The actual trajectory a parcel takes does need to be considered, but a simple model of horizontal processing of air by passage through the Western Pacific cold point tropopause reasonably reproduces observed stratospheric humidity. Variability in stratospheric water vapor on seasonal and interannual timescales has been well reproduced by climatological trajectory studies using saturation mixing ratios calculated from global temperature analyses, demonstrating that to first order, variability in the entry of water vapor into the stratosphere is controlled by variability in tropical cold point temperatures. Convection overshooting into the stratosphere has been observed on limited occasions, and when it occurs likely hydrates the stratosphere locally. However, evidence for a global impact of this phenomenon is lacking at this. Because

there is a relatively short turnover time for air in the lowermost stratosphere, on the order of months, changes in the entry value of water vapor to the stratosphere due to tropical cold point temperature changes will be seen almost immediately throughout the lowermost stratosphere. However, there will be a time lag before the signal reaches the middle and upper stratosphere on the order of years.

Accuracy of Stratospheric Water Vapor Measurements

Measuring low stratospheric water vapor concentrations is highly challenging and uncertain. There are significant discrepancies noted between coincident measurements of stratospheric water vapor concentrations using different *in situ* and satellite. These discrepancies range from 10 to 50% or even greater in some cases and preclude combining data sets for trend analysis without extreme care. This issue, of accuracy, is at the root of one of the current water vapor puzzles.

As moist air rises to colder regions in the atmosphere, in particular, in the region of the tropical tropopause, humidity rises above its equilibrium value over ice. As a consequence, the air releases its water vapor via ice cloud formation. These clouds form via ice nucleation in or on existing aerosol particles and then the ice particles grow through condensation of supersaturated water vapor onto the ice surfaces. Ice nucleation requires a supersaturation above a critical threshold value, which, for homogeneous freezing in the upper tropical troposphere, is $\sim 160\%$. Nucleation can also occur heterogeneously on particles known as ice nuclei. After nucleation, vapor molecules condense onto the ice particles, causing them to grow and the gas phase to become depleted in water until equilibrium is reached, and that equilibrium is assumed to be somewhere near 100% saturation. However, there are some observations of persistent clear air supersaturations with respect to ice greater than 200% and in cloudy air of 130%. This is a puzzle, because large supersaturations are expected to relax near 100% quite rapidly. The question remains as to whether these measurements, at quite low mixing ratios, are accurate. There has been a large international effort to attempt to address this accuracy issue; this effort has included instrument comparisons within a large cloud chamber (AquaVit), comparisons during aircraft missions, and consideration of calibration methods used at low mixing ratios. This effort is still ongoing.

As noted above, there are still concerns with absolute accuracy in measurements for stratospheric water vapor, however, data quality is sufficient to examine annual and interannual variations of water vapor in the tropical lower stratosphere as long as one considers long-term stable measurements. Many studies have shown that annual and interannual variations are to be in quantitative agreement with the idea that variations in tropical tropopause temperatures control the entry value of stratospheric water. The tropical annual variation, known as the water vapor tape recorder is an excellent example of the impact of tropical tropopause temperatures on water vapor. The level of coldest temperatures sets the water vapor mixing ratio; the correlation between temperature and water vapor is shown in Figure 4, with the dominant variation seen in the annual cycle. This annual variation in water vapor entering the stratosphere

Figure 4 The 5°N–5°S water vapor mixing ratio from HALOE at the altitude of the average profile minimum in the tropics (black solid, scale on left) and NCEP/NCAR reanalysis zonal average tropopause temperatures (gray dashed, scale on right). The correlation maximizes with a 2-month shift, with water vapor lagging. Reproduced from Rosenlof, K. H., Reid, G. C., 2008. Figure 5 Tropical HALOE water vapor (tape recorder), 5°S–5°N, plotted versus time. Note the change to lower values of the hygropause at the end of 2000 and the upward propagation of those lower values in subsequent years. Reproduced from Rosenlof, K. H., Reid, G. C., 2008. Trends in the temperature and water-vapor content of the tropical lower stratosphere: the sea-surface connection. *Journal of Geophysical Research* 113, D06107. doi:10.1029/2007JD009109.

then propagates upward, as seen in Figure 5. The ability for a model to reproduce this feature is commonly used to assess quality of a simulation, as it tests both the model's stratospheric overturning circulation and the degree of mixing between low and middle latitudes. Comparisons of water vapor simulations with observations have been used as one means for assessing the quality of chemistry climate model simulations in recent studies.

Long-Term Trends

Global water vapor trend determination from the historical record is difficult. There are differences in trends noted between

measurement systems covering the same time period (e.g., the northern hemisphere frost point balloon as compared with the UARS HALOE satellite instrument). The multidecadal stratospheric water vapor record is limited to northern hemisphere midlatitudes. The longest continuous record of stratospheric water vapor data is from frost point balloon measurements taken at 40°N from Boulder, Colorado. At present, the longest satellite records are from SAGE II and HALOE instruments, however, the MLS instrument is now building up a significant time record.

There are indications that the stratospheric water vapor has increased over the past 50 years. This is to be expected given that methane emissions have increased, and oxidation of methane is the major production of water vapor in the

Figure 6 One-year moving averages of the 2-km water vapor mixing ratio averages in each of the six altitude levels denoted on the panel. From Hurst, D. F., Oltmans, S. J., Vömel, H., Rosenlof, K. H., Davis, S., Ray, E. A., Hall, E., Jordan, A., 2011. Stratospheric water vapor trends over Boulder, Colorado: analysis of the 30 year Boulder record. *Journal of Geophysical Research* 116, D02306. doi:10.1029/2010JD015065.

stratosphere. However, some studies indicate that the increase in methane emissions may significantly exceed, hence the need to consider mechanisms that change the transport of water vapor into the stratosphere. For example, if there is a change in the transport of air into the stratosphere, with the fraction of air entering the stratosphere bypassing the changing coldest tropical temperatures, there could be, conceivably, a change in the effective entry value of stratospheric water vapor without a change in the contribution due to methane oxidation. **Figure 6** shows interannual variability and the long-term trend for water vapor from 1980 to 2010 from frost point balloon data taken at one location in the northern midlatitudes. Note the increase over time at multiple altitudes, and the multiyear variability as well. Understanding this record and the possible feedbacks associated with changes in stratosphere water is the subject of current research, and encompasses studies of chemistry, dynamics, and radiation.

Summary

There is good understanding of the spatial distribution of water in the stratosphere as well as what drives the annual cycle of water vapor entering the stratosphere. The amplitude of the annual cycle is 50–60% of the mean and well explained by the known annual cycle in tropical tropopause temperatures. In contrast, the trend in stratospheric water vapor, which is a much smaller signal than the annual cycle, is not well understood. Over the period 1950–2000 there was an increase in the entry-level stratospheric water vapor on the order of 1% per year during a period of increasing tropospheric methane and decreasing tropopause temperatures. At the end of 2000, there was a decrease in the stratospheric entry-level water vapor coincident with a steplike drop in tropical tropopause temperatures. The observed long-term increase in stratospheric water vapor over the 1950–2000 period cannot be explained through tropical tropopause temperature trends, although many aspects of interannual variability can be. The more recent decrease in stratospheric water vapor can be explained by tropical tropopause temperature changes, although the mechanism driving that temperature change is

not well understood. Measurements are difficult to make with extremely high accuracy, and there are still questions as to whether high supersaturations that have been measured by *in situ* instruments are valid. This impacts our understanding of microphysical processes, and is a topic of current research. Because of the uncertainties in our understanding and modeling of past water vapor changes, it is difficult to predict changes expected in a future climate.

Introduction

The troposphere and the stratosphere are separated by a boundary called the tropopause, whose altitude varies from about 16 km in the tropics to about 8 km near the poles. The troposphere is characterized by rapid vertical transport and mixing caused by weather disturbances; the stratosphere is characterized by very weak vertical transport and mixing. The tropopause thus represents a boundary between the troposphere, where chemical constituents tend to be well mixed; and the stratosphere, where chemical constituents tend to have strong vertical gradients. The two-way exchange of material that occurs across the tropopause is important for determining the climate and chemical composition of the upper troposphere and the lower stratosphere. This cross-tropopause transport is referred to as stratosphere–troposphere exchange. The upward transport of tropospheric constituents into the stratosphere occurs primarily in the tropics, and initiates much of the chemistry that is responsible for global ozone depletion. The downward transport of stratospheric constituents into the troposphere occurs mostly in the extratropics and not only serves as the major sink for some of the constituents involved in stratospheric ozone depletion, but also provides a source of upper tropospheric ozone.

This pattern of upward cross-tropopause transport in the tropics and downward cross-tropopause transport in the extratropics is part of a global mass circulation in the stratosphere that occurs as an indirect response to zonal (westward) forcing in the stratosphere, which is caused by the breaking of large-scale waves propagating from the troposphere. The magnitude and variability of this stratospheric mass circulation, and its consequences for atmospheric chemistry, are primary considerations in the study of stratosphere–troposphere exchange.

The Dynamics of Mean Mass Exchange

The Dynamical Definition of the Tropopause

The tropopause is traditionally defined by meteorologists as the lowest level at which the rate of decrease of temperature with respect to height (normally about 6 K km^{-1} in the troposphere) decreases to 2 K km^{-1} , and the average from this level to any level within the next 2 km does not exceed 2 K km^{-1} . This definition, however, does not always clearly mark the boundary between stratospheric and tropospheric air. The physical tropopause is better defined in terms of a specified critical value for a long-lived tracer such as ozone, which has distinctly different stratospheric and tropospheric values. Because global observations of ozone in the vicinity of the tropopause are very limited, it has become common to use as an alternative marker for the tropopause a dynamical field called the potential vorticity. Potential vorticity is somewhat analogous to spin angular momentum. For large-scale atmospheric motions potential vorticity is approximately given by $P = \rho^{-1} - (\zeta + f)(\partial\theta/\partial z)$, where ρ is the air density, ζ is the vertical component of relative vorticity, f is the Coriolis parameter (twice the local vertical component of the Earth's angular velocity), θ is the potential temperature (a measure of entropy, which increases rapidly with height in the stratosphere), and z is the height above sea level. Since $\partial z/\partial\theta$ may be regarded as a local measure of the depth of the layer between two potential temperature surfaces, an increase in $\partial z/\partial\theta$ implies stretching of vortex tubes and an increase in the absolute vorticity, while a decrease in $\partial z/\partial\theta$ implies shrinking of vortex tubes and a decrease in the absolute vorticity; this is somewhat like the spin angular momentum of a ballerina or figure skater.

Outside the tropics, potential vorticity is positively correlated with ozone in the extratropical lower stratosphere, and is

a particularly suitable tracer for defining the tropopause. Potential vorticity increases dramatically from troposphere to stratosphere, and it can be readily calculated from conventional wind and temperature data. As shown in Figure 1, the tropopause defined in terms of a critical value of potential vorticity does not coincide with an isentropic surface, but rather cuts across the isentropes as it slopes downward toward the poles in midlatitudes. The region of the stratosphere where the isentropes intersect the tropopause is called the 'lowermost stratosphere,' and must be clearly distinguished from the region above where the isentropes lie entirely in the stratosphere. This latter region is often referred to as the 'overworld.'

The Diabatic Circulation

Potential temperature is a function of specific entropy alone and is thus conserved by fluid parcels when the motion is adiabatic. Since diabatic processes operate on the timescale of weeks in the lower stratosphere, on shorter timescales parcels move approximately along constant potential temperature surfaces. Transfer of mass and chemical constituents from the troposphere into the stratospheric overworld, however, clearly requires motion across isentropic surfaces. This transport is accomplished by a mean meridional cross isentropic mass circulation. Such a circulation was first deduced by Brewer and Dobson, who showed that observations of the stratospheric distributions of water vapor and ozone were consistent with the notion that upward transport in the stratosphere is limited to the tropics, while downward transport occurs in the extratropics. Thus, the stratosphere is dehydrated by the freeze drying of air passing upward through the extremely cold tropical tropopause, and ozone accumulates at high latitudes in the lower stratosphere through poleward and downward transport from its source region in the upper tropical stratosphere.

This transport circulation is now commonly referred to as the Brewer–Dobson circulation. It is often called the 'diabatic circulation,' since it is associated with the diabatic processes of

radiative heating and upward motion across isentropes in the tropics, and with radiative cooling and downward motion across the isentropes in the extratropics. For long-lived trace constituents, such as methane and nitrous oxide, this pattern of meridional overturning, moving up in the tropics and down in the extratropics, tends to produce surfaces of constant mixing ratio that are elevated in the tropics and slope downward toward the poles, while mixing along the isentropes by planetary waves tends to flatten the slopes of surfaces of constant tracer mixing ratio.

Although it is associated with diabatic heating and cooling, the Brewer–Dobson circulation is not forced by radiative heating, nor is it forced directly from below by penetration of convection into the stratosphere. Rather, it is a nonlocal response to an extratropical wave-driven pumping action. This pumping is caused by the wave-induced westward force in the extratropical stratosphere. Because the Earth is rotating rapidly, pushing air westward produces a gyroscopic effect in which the air drifts poleward. By mass continuity a poleward drift in midlatitudes is compensated by upward motion accompanied by expansion and adiabatic cooling in the tropics and downward motion accompanied by compression and adiabatic warming in the extratropics (Figure 2). This distribution of adiabatic cooling and heating maintains the temperature below radiative equilibrium in the tropical upwelling region, and above radiative equilibrium in the extratropics. Thus, the distribution of radiative heating and cooling in the stratosphere does not drive the mean meridional mass flow, rather it is a response to the dynamically driven mass flow.

Rossby Waves

Wave driving in the extratropical stratosphere is caused primarily by Rossby wave breaking. Rossby waves owe their existence to the latitudinal gradient of potential vorticity along isentropic surfaces. Because of this gradient, a fluid parcel displaced poleward or equatorward (and materially conserving its

Figure 1 Latitude–altitude cross section for January 1993 showing longitudinally averaged potential temperature (solid contours) and temperature (dashed contours). The heavy solid contour (cutoff at the 380 K potential temperature surface) denotes a constant potential vorticity contour, which approximates the tropopause outside the tropics. Shaded areas denote the 'lowermost stratosphere' region whose potential temperature surfaces span the tropopause. Reproduced from Holton, J.R., Haynes, P.H., McIntyre, M.E., et al., 1995. Stratosphere–Troposphere exchange. *Reviews of Geophysics* 33, 403–439.

Figure 2 Dynamical aspects of stratosphere–troposphere exchange. The tropopause, defined by a specified constant potential vorticity in the extratropics and the 380 K potential temperature surface in the tropics, is shown by the thick line. Thin lines are potential temperature surfaces labeled in Kelvin. The shaded region is the ‘lowermost stratosphere’ where potential temperature surfaces intersect the tropopause, and isentropic exchange by tropopause folding occurs. Light shading in the stratosphere denotes the wave-induced westward zonal force. Wavy arrows indicate quasiisentropic transport and mixing by large-scale waves. The two-way exchange results in blocking of anticyclones, cyclone cutoff, and tropopause folds in the troposphere. The broad horizontal arrows are the meridional drift that balances the wave-induced zonal force, and the broad vertical arrows show the nonlocally driven equatorial upwelling and extratropical downwelling referred to here as the diabatic circulation. In the tropics some cumulonimbus clouds penetrate the stratosphere. Reproduced from Holton, J.R., Haynes, P.H., McIntyre, M.E., et al., 1995. Stratosphere–Troposphere exchange. *Reviews of Geophysics* 33, 403–439.

potential vorticity) will have potential vorticity different from that in the local environment and will induce a perturbation velocity disturbance. This will cause parcel displacements of the same sign to the west of the original displaced parcel, and of the opposite sign to the east. The result is a wave pattern in the potential vorticity field that propagates westward relative to the mean flow. When such a wave breaks in the stratosphere it produces a westward directed zonal force or wave drag (see *Dynamical Meteorology: Rossby Waves*).

Global Exchange: The Lowermost Stratosphere and the Overworld

Global mass exchange into and out of the chemically important region of the stratosphere is to a large degree controlled by the extratropical wave-driven pump discussed above. Air in the overworld, where isentropic surfaces lie entirely in the stratosphere, cannot reach the troposphere without first slowly descending across isentropic surfaces, a process that must be accompanied by diabatic cooling. The isentropic surface bounding the overworld and the lowermost stratosphere generally has a potential temperature around 380 K, depending on cloud top heights (see [Figure 2](#)).

The distinction between the overworld and the lowermost stratosphere implies that it is not always essential to measure

stratosphere–troposphere exchange by the transport across the tropopause.

For many purposes, transport into and out of the stratospheric overworld may be more relevant, and more effectively evaluated. For example, consider the case of a chemical species such as methane (CH_4) that has a tropospheric source and a stratospheric sink, with the sink being about 18 km or so, in the overworld. The transport across the 380 K potential temperature surface, which can largely be understood as part of the global-scale circulation of the overworld, is then an acceptable measure of exchange; indeed it is often more relevant because of the higher location of the photochemical sink. The same applies to a species that has a stratospheric source and a largely tropospheric sink. In this context, details of the transport across the tropopause are largely irrelevant.

For the understanding of mass and tracer transport into and out of the overworld, the replacement of the tropopause by a more convenient isobaric or isentropic control surface located in the lower stratosphere is useful. However, for some purposes, the mass transport across the actual tropopause is required. The net downward mass fluxes across the extratropical tropopause and across an isobaric or isentropic control surface that nearly coincides with the tropopause in the tropics should be equal for a sufficiently long time average. Such equality will not hold on seasonal or shorter time scales since the amount of mass in the layer between the extratropical

tropopause and an isobaric or isentropic surface coinciding with the tropical tropopause may vary with time.

To focus on the important aspects of global-scale exchange, it is useful to distinguish between the transport along isentropic surfaces, which can occur in rapid adiabatic motions (wavy arrows in Figure 2), and transport across isentropic surfaces, which requires diabatic processes. Since the tropopause intersects the isentropes, transport can occur in either way, and is likely to occur in both ways. In the region of the atmosphere called the lowermost stratosphere, where isentropic surface intersect the tropopause, air and chemical constituents can be irreversibly transported across the tropopause as adiabatic eddy motions lead to large latitudinal displacements of the tropopause, followed by irreversible mixing on small scales. The dark shading in Figure 2 shows the region within the lower stratosphere most directly affected by these eddy transport effects. The lowermost stratosphere must be distinguished from the rest of the stratosphere, being the only part of the stratosphere accessible from the troposphere via transport along isentropic surfaces.

Transport in the overworld must be clearly distinguished from transport in the lowermost stratosphere. Transport in the lowermost stratosphere requires consideration of the details of synoptic-scale and small-scale processes. Horizontal mixing can be especially significant in the lowermost stratosphere, especially during 'blocking' events, when meridional motions are enhanced. Thus exchange between the troposphere and the lowermost stratosphere can be significantly faster than exchange between the overworld and the lowermost stratosphere.

The Annual Cycle in Global Stratosphere–Troposphere Exchange

Diagnostics of the wave-driven zonal force in the extratropical stratosphere from analysis of conventional global meteorological data can be used to produce estimates of the vertical mass flux across a convenient control surface, such as the 100 hPa isobaric surface (~ 380 K potential temperature surface in the tropics), which can be regarded as approximating the lower boundary of the overworld. This technique works best for the solstice seasons, when the time change of zonal momentum is small compared to the wave-induced force. Results for the downward mass fluxes across the 100 hPa surface for the Northern and Southern Hemispheres (and by continuity the upward flux in the tropics) are shown in Table 1. The deduced

upward mass flux in the tropics is sufficient to completely replace the mass above the 100 hPa surface in about 2–2.5 years. The observations suggest that the mass transport across the tropical tropopause is twice as large in Northern Hemisphere winter as in Southern Hemisphere winter.

This deduced annual cycle in mass transport across the 100 hPa surface is consistent with the observed annual temperature cycle near the tropical tropopause, which is characterized by temperatures that are several degrees colder in January than in July throughout the tropics, and several degrees warmer in January than in July in the extratropics, as would be expected from the influence of the annual cycle in adiabatic cooling associated with the vertical motions. The annual cycle in mass transport is also consistent with the observed cycle in tropical total ozone, which is a minimum in February and a maximum in August, as would be expected from the enhanced vertical advection of ozone-poor tropospheric air into the tropical lower stratosphere during the Northern Hemisphere winter.

Isentropic Exchange in the Extratropics

As mentioned above, in midlatitudes the tropopause cuts across isentropic surfaces so that two-way stratosphere–troposphere exchange can occur through isentropic transport and mixing processes. Nevertheless, the boundary between stratospheric and tropospheric air remains very distinct in this region. This suggests that there must be a rather strong dynamical resistance to exchange along the isentropes. This resistance is supplied by the mechanism of Rossby wave propagation. Because of the strong isentropic gradient of potential vorticity that marks the tropopause in the lowermost stratosphere, there is a very strong Rossby wave restoring force in that region, which limits the extent of parcel displacements across the potential vorticity gradient. Hence, wave breaking only occurs for large-amplitude disturbances. Because there is a large store of available potential energy associated with the strong meridional temperature gradient in this region, large-amplitude weather disturbances quite frequently develop in this region, especially in wintertime. The vertical circulations associated with such disturbances create deep intrusions of stratospheric air into the troposphere, which may then become mixed with tropospheric air to produce irreversible transport into the troposphere. Much of the ozone transport from the lowermost stratosphere into the troposphere occurs in connection with such 'tropopause fold' events.

The quasiisentropic exchange initiated by tropopause folding could in theory occur in the absence of the diabatic circulation. But in that case there would necessarily be an equal quasiisentropic reverse transport of air from the troposphere into the stratosphere in order to maintain mass balance. The extremely low water vapor mixing ratios observed throughout the stratosphere indicates, however, that the quasiisentropic exchange in midlatitudes is mostly a one-way transport into the troposphere. Furthermore, the large-scale diabatic circulation is required to transport stratospheric constituents such as ozone downward from the overworld to the lowermost stratosphere. The average rate at which such a species can be transported into the troposphere is thus ultimately determined by the rate at

Table 1 Solstice season mass flux across the 100 hPa surface

Location	Mass flux ^a (10^6 kg s ⁻¹)		
	DJF	JJA	Annual mean

which the dynamically controlled large-scale circulation transports mass into the lowermost stratosphere. For this reason, the details of mesoscale tropopause fold events may not be important for determining the global flux of ozone from the stratosphere, although they will certainly strongly influence the time and space distribution of such transport.

Tracer Exchange in the Lowermost Stratosphere

Exchange of trace constituents cannot be treated in the simple manner used above for the net mass flux because net tracer exchange can occur in the absence of mass exchange. For example, if one unit of air containing a high ozone mixing ratio flows into the troposphere and an equal unit with low ozone mixing ratio flows into the stratosphere, there will be a net downward ozone flux, but zero net mass flux. This sort of process could lead to tracer exchange at the lower edge of the lowermost stratosphere, where the tropopause cuts across isentropic surfaces.

Such exchange does not, however, occur on a continuous basis. As noted above, the boundary between stratospheric and tropospheric air along isentropes that span the tropopause is normally marked by strong isentropic potential vorticity gradients. The existence of this band of strong potential vorticity gradients, and indeed similarly strong gradients in mixing ratios of species such as ozone and water vapor, itself suggests that there must be rather strong dynamical resistance to cross-tropopause transport along the isentropes, since otherwise vigorous mixing of stratospheric and tropospheric air would destroy the band of strong gradients.

Nevertheless, stratosphere–troposphere exchange of tracers can occur by isentropic transport in the extratropical region. Development of strong upper-level weather disturbances can lead to displacement of the tropopause from its equilibrium position, followed by nonconservative processes such as diabatic heating or cooling or small-scale turbulent mixing. It is only in the presence of such vigorous eddy motions near the tropopause that the dynamical resistance to cross-tropopause exchange can be overcome, and deep intrusions of stratospheric air can penetrate into the troposphere. These intrusions may also to some extent be regarded as the result of the systematic effect of the large-scale ageostrophic circulations associated with the development of frontal structures near the tropopause. The stretching deformation that occurs during frontal development stretches stratospheric intrusions to ever finer scales and leads to irreversible transport, often speeded up by turbulence resulting from shear instabilities. Much of the ozone transport from the lowermost stratosphere into the troposphere is believed to occur in connection with such tropopause fold events. Many studies have confirmed that large

episodic stratosphere–troposphere exchange can occur in association with tropopause folding.

The Role of Tropical Convection in Stratosphere–Troposphere Exchange

Although convection does not control the rate at which the diabatic circulation moves mass into or out of the overworld, penetrative convection may influence a layer a few kilometers in depth in the region of the tropical tropopause. This tropopause layer plays an essential role in establishing the stratospheric water vapor budget. Aircraft and satellite observations of the water vapor distribution in the tropical lower stratosphere reveal the existence of a water vapor mixing ratio minimum (referred to as the ‘hygropause’). The hygropause often occurs well above the tropopause. This feature is now believed to result from dehydration to the saturation mixing ratio at the tropopause (the freeze drying process), followed by vertical advection of the resulting minimum in water vapor mixing ratio into the overworld by the diabatic circulation. Since, as pointed out above, the tropical tropopause temperature is colder in Northern winter than in Northern summer, the driest air enters the stratosphere in Northern winter (when the hygropause is observed to be just above the tropopause), and is advected upward to produce the observed elevated hygropause near 19 km in Northern summer.

The tropopause separates the stratosphere from the troposphere. It is located at the interface between two air masses with distinctly different characteristics in water vapor, ozone, potential vorticity, and other chemical or physical quantities. Stratosphere–troposphere exchange (STE) refers to the processes whereby mass and chemical species are transported between these two atmospheric regions across the tropopause. This exchange is important to the chemistry of both regions as it regulates the transport of species with tropospheric sources into the stratosphere (e.g., chlorofluorocarbons (CFCs), water vapor, and hydrocarbons) and

species with stratospheric sources into the troposphere (e.g., ozone and nitric acid). In this article we identify and describe the small-scale processes occurring in the vicinity of the tropopause that govern this exchange. We distinguish between these processes and the large-scale regulation of the exchange by the zonal mean–meridional Brewer–Dobson circulation (Figure 1).

The Brewer–Dobson circulation, a circulation largely forced by wave breaking remote from the tropopause, acts to drive air parcels up through isentropic surfaces in the tropics (corresponding to a mean heating of the air parcels) and down

Figure 1 Dynamical aspects of stratosphere–troposphere exchange. The tropopause is shown by the thick line. Thin lines are isentropic surfaces labeled in Kelvin. The heavily shaded region is the 'lowermost stratosphere', where isentropic surfaces span the tropopause and isentropic exchange by tropopause folding occurs. The region above the 380 K surface is the 'overworld', in which isentropes lie entirely in the stratosphere. Light shading in the overworld denotes wave-induced forcing (the extratropical 'pump'). The broad arrows show transport by the global-scale circulation, which is driven by the extratropical pump. This global-scale circulation is the primary contribution to exchange across isentropic surfaces (e.g., the 400 K surface) that are entirely in the overworld. Reproduced with permission from Holton *et al.* (1995).

through the isentropic surfaces in the extratropics (corresponding to a mean cooling of the parcels). The dynamics of this circulation determines the net STE on an annual time scale. The upward branch of this circulation forces a net exchange from the troposphere to the stratosphere in the tropics and from the stratosphere to the troposphere in the extratropics. Small-scale processes influence precisely where and when STE of mass and chemical species occur. Modeling studies suggest the timing of the exchange, in particular, is important to tropospheric chemistry. Small-scale processes also influence the composition of the stratosphere in the vicinity of the tropopause. In particular, the composition of the lowermost extratropical stratosphere (the part of the stratosphere that shares isentropic surfaces with the troposphere) is strongly affected by small-scale processes.

The operational definition of the tropopause by the World Meteorological Organization is given in terms of the temperature lapse rate. However, in the extratropics a dynamically based definition of the tropopause is in terms of a potential vorticity (usually taken at a potential vorticity equal to $2 \times 10^{-6} \text{ m}^2 \text{ s}^{-1} \text{ K kg}^{-1}$). This definition cannot be extended to the tropics, where it is convenient to simply define the tropopause as the 380 K potential temperature surface. Regardless of the definition, the interface between stratospheric and tropospheric air masses forms a wavy surface with substantial geographic variations in height, latitude, and longitude. Significant displacements of the tropopause can occur without STE. The tropopause is a dynamic surface so that transport across it cannot be considered in the same manner as transport across a surface unaffected by transport (e.g., a constant altitude surface). For example, while the mean height of the Northern Hemisphere tropopause lowers during winter, the STE peaks in the spring months.

The advantage of using potential vorticity or potential temperature to mark the tropopause is that these quantities act as tracers of air mass motion, making them ideal to mark the interface between stratospheric and tropospheric air masses. Potential vorticity and potential temperature are conserved along trajectories except for the processes of diabatic heating (the vertical gradient of diabatic heating in the case of potential vorticity) and mixing. The extent to which these quantities are not conserved can be taken as a measure of the STE. Therefore, STE can be defined as the amount of mass or constituents transported across potential temperature surfaces in the tropics and potential vorticity surfaces in the extratropics. Diabatic heating and its vertical gradient are generally small in the upper troposphere and lower stratosphere. Mixing is also expected to be slow due to the high static stability of the stratosphere (which resists vertical displacements) and the high potential vorticity gradients (which resist horizontal displacements) of the lower extratropical stratosphere. However, as discussed later, under specific circumstances, these nonconservative processes are large enough to allow for significant STE.

Because of the different processes involved, the description of STE by small-scale processes is split between the tropics and extratropics. In each section we show how small-scale mixing and diabatic heating at the tropopause result in exchange between the troposphere and the stratosphere.

Although intensive research has taken place in the last 40 years, there are still a large number of uncertainties and unknowns in the small-scale processes involved in STE. In

particular, the precise mechanisms for the exchange across the tropical tropopause are still not completely understood.

Tropical Regions

The tropical tropopause (located at approximately 380 K) is located in the upwards branch of the Brewer–Dobson circulation (Figure 1) at a pressure of approximately 100 hPa and a temperature of approximately -70 to -80°C . Constituents lofted across the isentropic surface 400 K (approximately 90 hPa) subsequent to crossing the tropical tropopause are likely to be transported into the middle and upper stratosphere by the large-scale Brewer–Dobson circulation. There they can affect the composition of the stratosphere for years. Between the tropical tropopause and 400 K theoretical calculations and measurements of both water vapor and atomic bomb debris (from the 1950s and 1960s explosions) indicate considerable poleward transport of trace constituents. This suggests that a fraction of the constituents which cross the tropical tropopause are not transported much above 400 K, but are rapidly transported into the lowermost extratropical stratosphere, through mostly isentropic transport.

STE in the tropics is governed by a complex and poorly understood interplay between convection and the large-scale Brewer–Dobson circulation. Parcels that cross the tropopause are initially transported upwards in deep convective clouds. However, above some height, the Brewer–Dobson circulation will govern the subsequent uplift of the parcel. The transition height between convection and the large-scale circulation is not firmly fixed. At least the tropical tropopause is often not clearly demarcated. Instead it may be more accurate to regard the tropical tropopause as a rather deep transition region between the troposphere and the stratosphere.

It is still an open question whether the transition between convection and the large-scale circulation typically occurs above or below the defined tropical tropopause. Convective turrets do penetrate the tropopause on occasion, as observed in the Indonesian region, for example. However, there is some doubt as to whether these very deep convective events occur frequently enough to supply the requisite upward mass flux. In this case the upward motion across the tropical tropopause could be of large scale, in which case frequent high cloudiness near the tropopause would be expected. Subvisible cirrus clouds are observed over the warm pool of the western Pacific over 90% of the time during Northern Hemisphere winter, but the cause of this cloudiness is yet undetermined. On the other hand, if convection supplies more than the requisite mass flux above the tropopause, only the highest and coldest convective events may end up impacting the stratosphere. In this case, outside the convective updrafts the equatorial tropopause is in a subsident region.

The dryness of the air entering the equatorial stratosphere (approximately 3 ppm by volume during the Northern Hemisphere winter and 4.2 ppm by volume during Northern Hemisphere summer) tightly constrains the possible pathways through which tropical air can enter the stratosphere. As this is much drier than tropospheric air on average and typically drier than the saturation water vapor mixing ratio at the tropical tropopause, any theory of tropical STE must account for the dehydration of air parcels entering the stratosphere.

A possible mechanism for such low water vapor mixing ratio is that air that enters the stratosphere has been processed through a cloud. Indeed, as a parcel travels upward and cools, water in excess of the saturation vapor pressure condenses out. Efficient dehydration requires that the parcel remain at cold enough temperatures for ice crystals to grow to sufficient size for rapid sedimentation. Otherwise, as the parcel continues to rise into the stratosphere, the ice crystals may reevaporate. Air with low stratospheric mixing ratios of water vapor has sometimes been measured in association with deep convective clouds. However, processes other than convection may also play a role in dehydrating air. For example, gravity waves propagating near the tropopause may provide sufficient uplift to allow for additional condensation and loss of water vapor. Cloud processing will also affect the STE of chemical species through the attendant loss of soluble species.

Zonally averaged tropical tropopause temperatures are not consistent with the extreme dryness of the stratosphere. This suggests the hypothesis that there are preferred regions in which air enters the stratosphere; air passes locally upwards through the tropical tropopause only where the saturation vapor pressure is low enough (from the very cold temperatures) to allow for the sufficient dehydration of air parcels as described above. One such region occurs in the western Pacific (mostly in the vicinity of Indonesia) during Northern Hemisphere winter, in accord with the idea of a localized stratospheric 'fountain' through which air enters the stratosphere. However, during the Northern Hemisphere summer the temperature distribution from the large-scale meteorological analyses indicates no region with temperatures persistently cold enough to explain the water vapor record. At this time of year the cold temperatures and dehydration events must occur only sporadically in association with spatially and temporally restricted events not captured in the large-scale meteorological analyses. Another hypothesis, introduced recently and still being developed, is based on the existence of a deep tropopause transition layer. The dehydration of air occurs in convective systems but the transport of the dehydrated air into the stratosphere occurs in a slow ascent due to the overall net radiative heating in this part of the atmosphere. In this view, the dehydration and transport into the stratosphere occur at different times and locations. This view of tropical STE is more dynamic than the stratospheric 'fountain' and involves vertical and horizontal processes at very different scales. None of the hypotheses described above have yet been able to fully and consistently explain the observed distribution of water vapor in the tropical stratosphere.

Longitudinal variations in tropopause height and temperature, and therefore the preferred locations of equatorial STE, can be ascribed to an array of poorly understood local processes. The coldest tropopause heights are associated with the western Pacific warm pool and the Northern Hemisphere monsoon. This is consistent with convection playing an active role in shaping the morphology of the tropopause. However, the relationship between convection and the tropopause height is not straightforward. In particular, there is indication that minimum temperatures at the tropopause in January are centered on the Equator, while convection maximized slightly south. The radiative effects of convective clouds and the wave

motions forced by their diabatic heating obscure any straightforward relationship between convection, the height and temperature of the tropopause, and the location of STE.

Extratropics

Moving poleward from the Equator, the tropopause is conveniently defined in terms of a potential vorticity surface. STE occurs between the lowermost stratosphere and the troposphere through transport across this surface. While the transport can occur in either direction, it is predominantly from the stratosphere to the troposphere. The effect of transport in the opposite sense is short-lived due to the downwards large-scale mean meridional circulation, which acts to flush out the lowermost stratosphere within a relatively short period. In distinction to the tropical tropopause, the extratropical tropopause is usually clearly demarcated by strong gradients in potential vorticity and trace constituents.

The Subtropics

Stratosphere–troposphere exchange in this region occurs between the upper and mid-equatorial troposphere and the lowermost stratosphere. The subtropical tropopause drops rapidly near 30° from tropical heights to the level of the extratropical tropopause (approximately from 100 hPa to 300 hPa) (Figure 1). Trajectories from analyzed winds suggest very little STE occurs across this portion of the tropopause during the winter months but that considerable STE occurs during the summer months.

The subtropical tropopause cuts through the subtropical jet stream. This jet undergoes a substantial annual cycle in amplitude with the strongest winds occurring during the winter season. When the jet is strong, mixing across it between the troposphere and the stratosphere is inhibited; inhibited both through the large potential vorticity gradients associated with the jet, and the fact that breaking of tropospheric waves and the resulting mixing is unlikely to penetrate the jet core. Indeed, in the case of a strong jet the wind speeds are substantially larger than those associated with most tropospheric waves, implying that the critical layers (where the phase speed of the wave is equal to that of the large-scale flow field and therefore where the wave is unstable and breaks) will occur away from the jet core. During the summer months the subtropical jet weakens considerably, allowing mixing across the jet to be enhanced. Not only do the critical layers occur closer to the jet core during the summer months, but the smaller gradients of potential vorticity associated with the summer jet make for wider critical layers and weaker barriers to mixing.

The transport across the summertime subtropical jet is primarily associated with the Asian monsoon (Figure 2), and to a lesser extent the Mexican monsoon. While the monsoons of South America, Africa, and Australia probably play a similar role during the austral summer, their comparatively weak circulations are much less effective in transporting air across the tropopause. As indicated by the arrows in Figure 2, monsoon circulations are able to tap a particularly rich source of water vapor in the midlatitudes. The resulting STE is believed to be of primary importance to the seasonal cycle of water vapor in the

Figure 2 Schematic diagram of meridional transport and mixing adjacent to monsoon regions in northern summer, superposed on contours of zonal wind (interval 10 m s^{-1}). Heavy contours (interval 2 m s^{-1}) and one-way bold arrows indicate climatological meridional transport; two-way arrows illustrate mixing along isentropic surfaces. The large bold arrow at 30° N represents the western side of the Asian monsoon. Its direction should be reversed for the eastern side, where v (meridional velocity) is opposite and slightly smaller. The tropopause is shown (heavy dotted line, T) and the zero-wind line is labeled 0. Reproduced with permission from Dunkerton (1995).

extratropical lowermost stratosphere and does not involve the pronounced dehydration that occurs in the tropics.

The tropopause is elevated over monsoon regions with the associated anticyclonic circulation penetrating into the lowermost stratosphere. A steady state monsoon circulation will not in itself result in STE. However, due to the proximity of the monsoon circulation to the jet core, perturbations in the circulation are likely to be important, resulting in isentropic mixing between the troposphere and the stratosphere (Figure 2) and associated STE. Moreover, the interaction between monsoon and midlatitude synoptic disturbances or large-scale low-frequency transients will act to transport species across the tropopause. It has been demonstrated in the case of the Asian monsoon that the interaction can act to pull filaments (see the following section on extratropical STE) of moist tropospheric air into the stratosphere, and filaments of dry stratospheric air into the troposphere.

The Extratropics

In the extratropics a number of local processes result in STE. These include: stratospheric intrusions in the troposphere and their subsequent fragmentation; tropopause folds; cutoff lows; gravity waves; deep convection; radiative processes in the vicinity of the tropopause; and local dynamical instabilities. All the processes listed above are examined in more detail below.

The process of fragmentation (i.e., breaking into smaller and smaller structures such as filaments) of stratospheric intrusions is strongly related to isentropic mixing. Parcel advection calculations suggest that this mixing occurs vigorously throughout the year on isentropic surfaces below 330 K and is therefore responsible for most of the STE. The

fragmentation of stratospheric intrusions occurs as the large-scale velocity field causes tongues of stratospheric air to undergo large latitudinal excursions (Figure 3). Subsequently, these tongues can stretch and thin until they become mere filaments of stratospheric air embedded in the troposphere. This process can be viewed as the fragmentation of the tropopause itself. Once the filaments reach small enough scales they are rapidly and irreversibly mixed into the troposphere. This final mixing may occur due to dynamical instabilities growing at the interface of the filaments (e.g., Kelvin-Helmholtz shearing instabilities) (Figure 4) or through radiative decay. The associated potential vorticity anomalies become increasingly susceptible to radiative decay as they are stretched to small scales. Satellite measurements of ozone and water vapor suggest that fragmentation occurs continually in the vicinity of the tropopause.

The fragmentation of intrusions across the tropopause is similar to the fragmentation of the polar stratospheric vortex, creating the so-called stratospheric 'surf' zone. In both processes the associated irreversible mixing can be traced to the large meridional parcel displacements that occur in the vicinity of a Rossby wave's critical layer. As only large-scale waves can propagate into the stratosphere (due to the vertical structure of the zonal wind), the waves which break near the tropopause are of much smaller scale (generally wave number 4–7) than those that break higher up. Consequently the mixing regions are of smaller scale. The waves that break at the tropopause can often be linked to baroclinic instability. Depending on the horizontal shear of the flow, the mixing can occur on the equatorward side of the jet stream, in which case stratospheric air extrudes anticyclonically into the troposphere. In cases of enhanced horizontal shear, mixing can occur on the poleward

Figure 3 (a) Isentropic contours of potential vorticity on the 320 K surface for 14 May 1992, at 1200 UT, calculated from European Centre for Medium-Range Weather Forecasts (ECMWF) operational analyses. The black structures in the upper-left and right are indicative of dry stratospheric air.

side of the jet, in which case tropospheric air is entrained into the stratosphere.

Owing to the large potential vorticity jump across the tropopause, strong ageostrophic circulations are often created

in association with baroclinic wave-breaking events. The ageostrophic circulations enhance the deformation fields due to the large-scale winds and drive stratospheric air deep into the troposphere along isentropic surfaces. During these tropopause

Figure 4 Cross-section of tropopause fold event on 20 April 1984. Color-scale displays of (a) relative aerosol distributions and (b) ozone mixing ratios. In each case, the higher values of the parameter are indicated by yellow and orange. The mixing of the fold by shearing instabilities can be seen at its leftmost edge.

folding events, sheets of stratospheric air with a small vertical to horizontal aspect ratio become embedded deep within the troposphere. The ageostrophic circulation associated with tropopause folding is transverse to the jet, with the strongest downward motion generally occurring in the northerly flow to the west of the upper level trough, near the jet entrance region (point A [Figure 5](#)). The exchange is associated with both mixing and diabatic processes. The mixing occurs mostly in areas of strong upward and downward motion, as shown by several high-resolution modeling studies. Diabatic effects (latent heat release in clouds and radiative heating/cooling in the vicinity of

clouds) seem to occur mostly in the center of the curvature of the jet stream. Significant STE occurs during this process. In fact, tropopause folding is considered the most evident form of STE.

Under some circumstances tropospheric or stratospheric filaments wind up so as to consist of interwoven regions of stratospheric and tropospheric air. This can create medium-scale potential vorticity anomalies; positive when stratospheric filaments wind up in the troposphere, and negative when tropospheric filaments wind up in the stratosphere. These anomalies will typically be associated with closed circulations – circulations that are temporarily resilient to deformation by the

Figure 5 Three-dimensional view of the tropopause (PV2 PVU) during a tropopause folding. The jet entrance (exit) is indicated by A (B). Due to the ageostrophic circulation, the tropopause undergoes a strong downward motion at the western edge of the fold, followed by a strong upward motion at the eastern edge of the fold. large-scale flow field. The corresponding cutoff cyclones (when a high potential vorticity region becomes trapped in the troposphere) and cutoff anticyclones (when a low potential vorticity region becomes trapped in the troposphere), are often rather long-lived, subject only to slow decay through mixing and turbulent processes, radiative processes, and convective mixing (in the cutoff cyclones). All the above processes will result in STE.

Other processes may also contribute to extratropical STE. Because potential vorticity is not conserved in the presence of a heating rate gradient, radiative heating in the vicinity of the tropopause is likely to be important, for example, the local heating induced by the high cirrus cloud shield associated with synoptic storms. Lidar (light detection and ranging) ozone measurements and high-resolution modeling suggest that gravity waves excited at the surface by strong winds over steep terrain may at times be responsible for mixing at the tropopause level. Strong thunderstorms in the extratropics occasionally penetrate the tropopause, presumably resulting in STE, although the effect of these storms has not been adequately documented. Both extratropical convection and topographic gravity waves will only result in STE under specific conditions: topographically forced gravity waves only occur under specific wind conditions and intense convection is most likely to during the summer months and over land. While it is difficult to extrapolate from local events to their global effects, the global importance of these processes is likely to be small, although their local effects may be significant.

Synopsis

The tropopause is an important boundary layer in Earth's atmosphere dividing the lowermost atmospheric layer, the troposphere, from the stratosphere. Depending on the geographical region, it can be found at a height of between 6 and 18 km. The troposphere is characterized by the weather conditions. The stratosphere is stably stratified due to an increasing temperature with height that is caused by a pronounced ozone layer at a height of between about 15 and 30 km.

Introduction

The tropopause denotes the natural limit between the troposphere (Greek *tropos* = turn; troposphere = turning or mixing sphere) and the stratosphere (stratified as opposed to mixed). These two atmospheric regions differ in various dynamical and chemical parameters, such as the vertical temperature structure, the potential vorticity, and the concentration of climatically relevant chemical species (e.g., ozone and water vapor). The tropopause is often obvious in observations or analyses of these dynamical and chemical parameters. In particular, high-resolution radiosonde measurements of the thermal and wind structure of the extratropical tropopause region exhibit a strong increase of temperature just above a sharp local cold-point tropopause. In a tropopause-based coordinate system, a persistent inversion is clearly identified in a narrow layer above the tropopause. However, in order to compile quantitative statistics of tropopause properties, one needs an objective definition that picks out the tropopause as accurately as possible. The tropopause can be defined in terms of physical parameters. The tropopause can exist anywhere between about 70 hPa (~18 km) and 400 hPa (~6 km), and it is therefore not convenient to use a constant pressure level to describe the tropopause. In the tropics, the tropopause is generally located at higher altitudes than in polar regions; the height of the tropopause depends on the season and is affected by weather conditions in the troposphere. Long-term changes are observed, and it has been proposed that the tropopause height can be used as a robust indicator of climate change.

Thermal Definition of the Tropopause

The conventional ('classical') definition of the tropopause is based on differences in the temperature lapse rates between stratospheric and tropospheric air. In the turbulently mixed troposphere, the temperature generally decreases with height. In the stably stratified stratosphere, the temperature increases with height owing to the absorption of solar ultraviolet radiation in the ozone layer (*see Ozone Depletion and Related Topics: Ozone as a UV Filter*). In 1957, the World Meteorological Organization (WMO) defined the thermal tropopause as the lowest level at which the lapse rate decreases to 2 K km^{-1} or less, provided that the average lapse rate between this level and all higher levels within 2 km does not exceed 2 K km^{-1} . The latter condition eliminates stable layers in the planetary boundary

layer (*see Boundary Layer (Atmospheric) and Air Pollution: Stably Stratified Boundary Layer*), which occasionally occur over high-latitude continents during winter, leading to the erroneous assignment of a tropopause level. The thermal WMO criterion is operationally applied to determine the tropopause height from individual radiosonde temperature soundings.

The main advantage of the thermal tropopause definition can be seen in its simplicity. In order to determine the tropopause, the vertical profile of only the temperature needs to be provided, which is in most cases well known. The thermal definition can be globally applied. However, this definition of the tropopause may lead to ambiguities owing to the presence of multiple stable layers, particularly in the vicinity of the jet streams (*see Synoptic Meteorology: Jet Streaks*). A further disadvantage is that the temperature lapse rate is not conserved in adiabatic flow. This may lead to large displacements of the tropopause during changes in the static stability by convergence. Moreover, the thermal definition obscures the fact that the tropopause often behaves as if it were a material surface to varying degrees of approximation.

Dynamical Definition of the Tropopause

A second definition of the tropopause is based on dynamical features. This definition employs the isentropic potential vorticity P , which can be expressed mathematically as in eqn [1].

$$P = -g(f + \zeta_\theta)\partial\Omega/\partial p \quad [1]$$

Here, g denotes the acceleration of gravity, f is the Coriolis parameter ($=2\Omega \sin\phi$), ζ_θ is the relative vorticity along an isentropic surface, θ is the potential temperature, p is the atmospheric pressure, and ϕ is the geographical latitude. The location of the so-called dynamical tropopause is assigned to the position where the potential vorticity P reaches a critical value. The tropopause separates low values of P in the troposphere from high values in the stratosphere. The WMO defines the dynamical tropopause by the threshold value of $P = 1.6 \text{ PVU}$, where PVU stands for 'potential vorticity unit' ($1 \text{ PVU} = 1 \times 10^{-6} \text{ K m}^2 \text{ kg}^{-1} \text{ s}^{-1}$). The potential vorticity is determined by both the stability and the three-dimensional wind field and is conserved in adiabatic flow. Compared to the thermal definition, this guarantees a better spatial and temporal continuity of the dynamically defined tropopause. Therefore, the dynamical method is sometimes superior to the thermal approach, especially in the vicinity of developing

baroclinic disturbances. However, the potential vorticity approach fails in the tropics, since the vertical component of absolute vorticity ($f + \zeta_\theta$) changes the sign at the Equator. Hence, the dynamical method of defining the tropopause is applicable only poleward of 10° latitude. Similar limitations exist even in the extratropical regions, where P locally becomes small within strong anticyclonic flows.

In the literature, threshold values defining the dynamical tropopause range from 1 to 5 PVU. A systematic global analysis using P -values ranging from 2 to 5 PVU indicated that the tropopause pressure was generally overestimated for values less than 3 PVU and systematically underestimated for values greater than 4 PVU compared to the pressure of the thermal tropopause. Grewe and Dameris employed 10-year statistics based on global data of the European Centre for Medium-Range Weather Forecasts (ECMWF) and found that a value of 3 PVU represents an acceptable value for the tropopause, especially in midlatitudes of the winter hemisphere. Additionally, they showed that values of P calculated at the height of the thermally defined tropopause exceed at least 2 PVU, independently of the season. This indicates that, following the WMO criteria, the 1.6 PVU surface generally lies below the thermally defined tropopause. However, Hoinka and coworkers pointed out that the 1.6 PVU tropopause well describes variability in space and time in comparison with tropopauses determined from radiosonde measurements. **Figure 1** shows a comparison of calculated zonal mean values

for a single day that can be employed to estimate the height of the tropopause. It is obvious that the extratropical thermal tropopause corresponds roughly to a constant potential vorticity surface of about 3 PVU.

The Tropopause as a Chemical Transition Layer

There are many measurements of chemical species in the upper troposphere and the lower stratosphere indicating an abrupt transition of mixing ratios and concentrations of chemical compounds in the vicinity of the thermal-dynamical tropopause. The most prominent examples are ozone and water vapor.

Mean tropospheric ozone concentrations in northern midlatitudes are typically less than $1 \times 10^{18} \text{ m}^{-3}$, showing no clear vertical gradient. In the lower stratosphere, ozone concentrations steadily increase up to (mean) maximum ozone values of $5 \times 10^{18} \text{ m}^{-3}$ at around 22 km height. The transition layer of low tropospheric to high stratospheric ozone concentrations is near the tropopause. The 'ozone tropopause' (ozonopause) is mostly found below the thermal tropopause. For example, in midlatitudes of the Northern Hemisphere, the ozonopause is located about 800 m below the thermal tropopause. So far, no official definition of the ozonopause has been released by the WMO. Based on the analysis of about 600 ozone sonde profiles at different stations in Northern Europe

Figure 1 Zonally averaged values of potential vorticity P (thin dashed and thin solid lines, units in PVU; see text), geometric height (heavy lines, in km), and the thermally defined tropopause (heavy dashed line) for 1 January 1985. Reproduced from Grewe, V., Dameris, M., 1996. Calculating the global mass exchange between stratosphere and troposphere. *Annales de Geophysique* 14, 431–442.

between 1991 and 1994, Bethan and coworkers have suggested defining the 'ozone tropopause' as the lowest height at which the following three conditions are valid:

1. The vertical gradient of the ozone mixing ratio is greater than 60 ppbv (60 ppb (10^{-9}) by volume) per kilometer, calculated over a height of 200 m.
2. The ozone mixing ratio exceeds 80 ppbv.
3. The ozone mixing ratio directly above the tropopause is greater than 100 ppbv.

Water vapor mixing ratios decrease strongly with height within the troposphere. Lower tropospheric mixing ratios are typically greater than 1000 ppmv (1000 ppm (10^{-6}) by volume), depending on the geographical region and season. The strong vertical gradient in water vapor profiles is obvious up to heights near the tropopause, the so-called hygropause. The existence of a significant decrease in the water vapor mixing ratio above the hygropause in midlatitudes had been evident from the first measurements, which were reported in 1946. For example, in the Northern Hemisphere, lower-stratosphere mean water vapor mixing ratio values of 3–5 ppmv are measured. The hygropause was discovered in the tropics more than three decades later, in 1979. A detailed global analysis of tropopause water vapor mixing ratios (beside other tropopause parameters) was given by Hoinka in 1999, employing ECMWF analyses in combination with in situ and satellite data for water vapor. He found that the tropopause mixing ratio of water vapor reaches a minimum in the tropics above the Pacific and Indian Oceans.

Distribution of the Tropopause Height

Ignoring the various possibilities for defining the tropopause, which yield some differences in determination of the pressure (see [Figure 1](#)), the tropopause pressure depends strongly on the geographical latitude, season, and type of location (continental or oceanic). Hoinka carried out a detailed statistical analysis of global tropopause pressure, employing data provided by the ECMWF for the period between 1979 and 1993. His analysis of the frequency distribution of the tropopause pressure above tropical, midlatitude, and polar regions, classified according to continental and oceanic areas, yielded the following:

- Above the Southern Hemisphere, the tropopause is of more zonal character than above the Northern Hemisphere, where the continents generate zonal wave patterns.
- Above both hemispheres, the strongest meridional gradients in the tropopause pressure are found between 20° and 40° latitude.
- Strong standard deviations in tropopause pressure are observed in the regions of the Atlantic and Pacific storm tracks.

Conclusions

The explanations given so far assume implicitly that the tropopause is a two-dimensional surface. However, due to recent analyses and investigations, it may be more useful to think of a 'tropopause zone' or a 'tropopause layer' that is a few

kilometers thick and in which vertical and horizontal mixing are both significant. Highwood and Hoskins discussed the results of several studies that seem to indicate that the tropical tropopause is generally far from being a single well-defined level. Gettelman and Forster defined a 'Tropical Tropopause Layer' (TTL) as the layer between the level of maximum convective outflow and the cold-point tropopause. Another definition has been provided by Fueglistaler and coworkers as a shallower layer between the level of zero clear-sky radiative heating and the cold-point tropopause (15–19 km). A layer of finite depth is also defined for the extratropics (i.e., the extratropical tropopause transition layer (ExTL)). Shepherd interpreted the transition as the result of recurrent wave-breaking events, forced by synoptic-scale baroclinic disturbances stirring tropospheric and stratospheric air masses with different chemical characteristics. Hegglin and coworkers showed that the ExTL is a global feature with increasing depth toward higher latitudes, and has been found to be different for different chemical tracers.

Nevertheless, it is important to know the temporal and spatial structure of the tropopause and of meteorological and chemical parameters within the transition zone between the troposphere and the stratosphere. This is necessary in order to estimate the exchange of mass, water vapor, ozone, and other chemical compounds between these two atmospheric layers. The transport of mass through the tropopause is for many purposes a useful measure of global-scale stratosphere–troposphere exchange (see **Stratosphere/Troposphere Exchange and Structure: Global Aspects**), in particular on seasonal or longer time scales. Detailed knowledge of the air mass exchange between the stratosphere and the troposphere is required for reliable estimates of the effects of natural and anthropogenic emissions on atmospheric composition and therefore on climate; it must be understood for the prediction of global change.

Synopsis

Anticyclones are horizontal circulations around relatively high sea-level pressure or high geopotential height on isobaric surfaces aloft. The structure, climatology, dynamics, and impacts of anticyclones are reviewed. Special kinds of anticyclones, such as blocking highs, subtropical highs, and stratospheric anticyclones associated with sudden stratospheric warmings are considered.

Introduction

Anticyclones are regions of relatively high pressure on horizontal surfaces, or high geopotential height on isobaric surfaces, around which air circulates clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere. Anticyclones are therefore characterized by negative relative vorticity and low but positive absolute vorticity in the Northern Hemisphere, while in the Southern Hemisphere they are distinguished by positive relative vorticity and low but negative absolute vorticity. On sea-level pressure or geopotential height analyses, they may be subjectively identified by closed isobars or height contours, whereas in vorticity analyses they may be objectively identified by relative vorticity minima in the Northern Hemisphere and maxima in the Southern Hemisphere.

At sea level, anticyclones typically originate as cold, shallow circulations that migrate equatorward and evolve into warm, subtropical high-pressure systems penetrating well into the troposphere. Aloft, anticyclones may appear at middle and high latitudes on isobaric surfaces. From hydrostatic considerations, these are relatively warm systems. Anticyclones aloft are often stationary or westward drifting and thus may block the eastward progress of other weather systems. Anticyclonic circulations at high latitudes may penetrate into the stratosphere where they may be associated with sudden stratospheric warmings (SSWs).

Although not as actively researched as cyclones, anticyclones are important because the clear, dry conditions usually associated with them may allow strong nighttime radiative cooling and cold surface temperatures. The convectively stable air of anticyclones may allow air pollutants to concentrate near

the earth's surface. Finally, the blocking action of anticyclones aloft may cause persistently anomalous weather conditions at the earth's surface.

Structure

Anticyclones may either be cold-core or warm-core systems. An example of each type is presented in **Figures 1** and **2**, respectively. Cold-core anticyclones are typically found on the poleward side of the midlatitude baroclinic zone. These are shallow systems with an anticyclonic circulation confined to the lower troposphere. The geostrophic relative vorticity (curvature in the isobars or geopotential height contours) is anticyclonic near the earth's surface but becomes cyclonic (or less anticyclonic) by the middle troposphere. The region of high sea-level pressure over northwestern North America in **Figure 1** is a cold-core anticyclone; notice its proximity to a local minimum in the 1000–500 mb thickness which, hydrostatically, is proportional to the vertically averaged temperature in the 1000–500 mb layer. This sea-level anticyclone is located between cyclonic and anticyclonic features at the 500-mb level (not shown).

Warm-core anticyclones are found equatorward of baroclinic zones and are characterized by circulations that remain or may become increasingly anticyclonic from sea level to the middle troposphere. The region of high sea-level pressure over the eastern Pacific Ocean in **Figure 2** is a warm-core anticyclone. Notice that it is located in a region of relatively high 1000–500 mb thickness (vertically averaged lower tropospheric temperatures) on the equatorward side of the midlatitude baroclinic zone (thickness gradient). This sea-level anticyclone is located directly beneath a closed, 500-mb anticyclone (not shown), indicating that it is a deep, warm system.

Both warm-core and cold-core anticyclones are characterized by gently subsiding vertical motion in the troposphere. This subsidence favors clear skies promoting strong nighttime radiative cooling of the earth's surface near the centers of these anticyclones. The adiabatic warming of the sinking air coupled with radiative cooling at the surface often produces an inversion in the vertical temperature profile; this inversion may be eroded or destroyed by daytime radiative heating and vertical mixing in the boundary layer. Regardless, anticyclones are distinguished by strong static stability.

Dynamics

Convergence of mass in the upper troposphere is the primary mechanism responsible for the relatively high sea-level pressure at anticyclone centers. From considerations of gradient wind balance, this mass convergence occurs downwind of anticyclonic circulations, or near regions of anticyclonic vorticity advection. The formation of new, cold-core anticyclones (or anticyclogenesis) is favored when this mass convergence occurs over a lower-tropospheric cold-air pool that, hydrostatically, would be associated with relatively high sea-level pressure. Warm anticyclogenesis may occur if mass convergence occurs over relatively high sea-level pressure at lower latitudes.

More commonly, cold anticyclones evolve into warm anticyclones as follows. The circulation around cold anticyclones draws cold air equatorward, forcing the sea-level pressure to locally rise. The anticyclone relocates toward rising sea-level pressure. Thus, cold anticyclones usually drift equatorward with time.

The mass convergence over the cold anticyclone forces air to sink through the troposphere and to adiabatically warm. The anticyclone thus becomes warmer over time and may eventually be located equatorward of the midlatitude baroclinic zone. Frictionally induced mass divergence at the earth's surface forces the sea-level pressure to fall at the anticyclone center, which then weakens. The anticyclone may reintensify as a warm system if mass convergence aloft exceeds in magnitude the lower tropospheric mass divergence near the anticyclone center. This is thought to be especially true of the quasistationary subtropical anticyclones, e.g., the Bermuda-Azores High of the Northern Hemisphere; mass convergence aloft associated with monsoonal circulations may help to maintain these systems.

Other mechanisms may contribute to anticyclone formation and intensification. While there is usually very little temperature advection in the lower troposphere over anticyclone centers, the advection of cold air in the upper troposphere and lower stratosphere over a sea-level anticyclone center may contribute to its intensification.

The convergence of mass in the upper troposphere over a developing or intensifying sea-level anticyclone is associated with sinking air and adiabatic warming in the troposphere, but rising air and adiabatic cooling in the stratosphere. Although vertical motions typically are an order of magnitude smaller in the stratosphere than in the troposphere, the static stability in the stratosphere is several orders of magnitude larger than that in the troposphere such that adiabatic temperature changes can be larger in the stratosphere than in the troposphere. Thus, while there is sinking motion and adiabatic warming in the troposphere over a developing or intensifying sea-level anticyclone center, there will be rising air and greater adiabatic cooling in the stratosphere, resulting in net cooling of the air column and, hydrostatically, sea-level pressure rises at the anticyclone center.

Clear conditions near cold anticyclone centers may result in the formation of ice fogs, and radiative heat loss from these fogs may contribute to sea-level pressure rises and anticyclone intensification. However, this effect is believed to be small. The sensible cooling of cold anticyclones by snow and ice-covered land surfaces may contribute to their formation and intensification. Similarly, the sensible cooling of warm anticyclones by relatively cool sea-surface temperatures over the eastern oceans favors these systems, especially during the warm seasons. Conversely, the sensible warming of cold anticyclones by relatively warm water in the cool seasons weakens these systems.

Climatology

Early climatologies of weather systems were constructed through manual inspection of sea-level pressure charts and subjective identification of centers of closed isobars.

Figure 1 Sea-level pressure (solid contours in millibars at 4 mb intervals) and 1000–500 mb thickness (colors in dekameters, at 60 m intervals) at 0000 UTC 23 January 2009. Notice the sea-level anticyclone (closed isobars around relatively high sea-level pressure) near 120° W, 60° N, collocated with an area of low 1000–500 mb thickness (vertically averaged temperature in the 1000–500 mb layer).

Figure 2 As in Figure 1 except at 0000 UTC 6 January 2009. Notice the sea-level anticyclone near 140° W, 30° N, collocated with an area of relatively high 1000–500 mb thickness.

Figure 3 Sea-level anticyclone track density, in number of centers per month, in the 1980–86 analyses of the European Center for Medium-Range Weather Forecasts. From Sinclair, M.R., Watterson, I.G., 1999. *Journal of Climate* 12, American Meteorological Society, Boston, pp. 3467–3485.

Figure 4 As in Figure 3 but for the Southern Hemisphere. From Sinclair, M.R., Watterson, I.G., 1999. *Journal of Climate* 12, American Meteorological Society, Boston, pp. 3467–3485.

Contemporary investigations employ automated procedures to objectively identify these systems from maxima in sea-level pressure analyses. Such investigations reveal that, over the Northern Hemisphere (Figure 3), sea-level anticyclones are most frequently analyzed in a band over the midlatitude Pacific Ocean, in a broad band near North America and centered on the Great Lakes, and near Mongolia. Over the Southern Hemisphere, similarly defined sea-level anticyclones are concentrated within a midlatitude (25° S– 45° S) band with little longitudinal variation (Figure 4).

In the middle troposphere over the Northern Hemisphere (Figure 5), anticyclones objectively identified from maxima in geopotential height fields are most frequently analyzed during the summer at low latitudes, especially over continental regions. During the winter these systems are rare but occasionally analyzed over high latitude oceans. These latter systems may be associated with blocking, as discussed below. No comparable results exist for the Southern Hemisphere to date, except for those anticyclones associated with blocking; these anticyclones are preferentially analyzed over the southern Pacific Ocean.

Blocking

Warm anticyclones that penetrate deep into the troposphere from the earth's surface in midlatitudes may, if stationary and persistent, block the normal eastward motion of other weather systems. Note that these are different from deep, warm subtropical anticyclones in that they are formed by the poleward breaking of midlatitude waves, resulting in a deep, warm

anticyclone that is detached from the warm air over the subtropics. As previously noted, subtropical anticyclones are formed by the equatorward drifting and warming of cold anticyclones, and are maintained by cold sea-surface temperatures and mass convergence aloft associated with monsoonal circulations.

Instead, a blocking anticyclonic circulation is maintained on its upstream flank by repeated fluxes of anticyclonic potential vorticity (lower tropospheric warm air and middle tropospheric anticyclonic vorticity). These fluxes are provided by smaller-scale waves approaching the blocking system, and help render the blocking anticyclone stationary and persistent. Additionally, the strong static stability of anticyclones helps maintain them against dissolution by convective mixing. Sinking motion in the statically stable, anticyclonic environment promotes adiabatic warming and maintenance of a deep, warm anticyclonic system.

Blocking anticyclones may be analyzed anywhere and at any time, but are favored during the cool season over the oceans, particularly the eastern oceans of the Northern Hemisphere and the eastern Pacific Ocean in the Southern Hemisphere. These locations are also downstream of the principal storm tracks and are also locations of climatologically preferred diffluent flow fields in the middle troposphere. The repeated interaction of small-scale systems with the diffluent flow enhances the diffidence (by making its poleward branch more anticyclonic) until an anticyclonic circulation is established aloft. Quasigeostrophically, this diffidence is enhanced by the local deposition of anticyclonic potential vorticity. Equatorward of the blocking anticyclone, the normal westerly flow may reverse to easterlies over a considerable longitudinal distance and for periods of a week or more. The blocking anticyclone

Figure 5 Number of twice-daily 500-mb geopotential height analyses during 1963–77 with anticyclones in 2° latitude by 5° grid boxes. From Bell, G.D., Bosart, L.F., 1989. *Monthly Weather Review*, vol. 117. American Meteorological Society, Boston, pp. 2142–2163.

may even penetrate into the stratosphere, causing a reversal of the zonal flow there from westerly to easterly and SSWs. In fact, almost all SSWs are preceded in time by recent tropospheric blocking events, but the converse is not true; blocking events are much more frequent than SSWs and thus are not necessarily each followed by an SSW.

An example of a blocking anticyclone is shown in [Figure 6](#). Notice the large 500-mb anticyclone over the eastern Atlantic Ocean, with highest 500-mb heights that are typical of much lower latitudes. An example of a stratospheric anticyclone is shown in [Figure 7](#). Notice the very large and broad anticyclone at 10 mb over northern North America. The zonally averaged zonal flow at 10 mb and 60° N reversed from westerly to easterly on the day of this analysis, defining an SSW. Although the analysis in [Figure 7](#) is 24 h after the analysis in [Figure 6](#), it is not known if the two phenomena are directly related or merely coincidental; the anticyclone in [Figure 7](#) may have resulted from the upward penetration of

a different, nonblocking anticyclonic circulation. Nevertheless, blocking anticyclones in general are of considerable scientific and practical importance.

Impact

Because they are characterized by clear skies and subsiding air, anticyclones are typically associated with fair weather. A stationary and persistent anticyclone may produce prolonged fair and dry weather conditions, depleting soil moisture, and stressing crops and water supplies. The strong stability of anticyclones may stagnate air near the earth's surface, leading to enhanced concentrations of pollutants. Clear skies near anticyclone centers favor strong nocturnal cooling near the earth's surface; these conditions during the growing season may damage crops. The equatorward circulation of cold air around anticyclones may cause sudden cold-air outbreaks over

Figure 6 An example of a blocking anticyclone. Color contours are 500-mb geopotential height, in meters, and the arrows are 500-mb horizontal winds, analyzed at 0000 UTC 22 January 1987. Notice the closed contours around relatively high 500-mb heights near 10° W, 52.5° N, and the easterly winds along 45° N from 20° W to 10° E.

Figure 7 An example of a stratospheric anticyclone associated with a sudden stratospheric warming. As in Figure 6 except for 10 mb and 0000 UTC 23 January 1987. Notice the large area of easterly flow from 35° N to 65° N and from 170° W to 100° W.

midlatitudes. The cold air associated with anticyclones may become wedged or dammed against mountain ranges, leading to freezing rain or ice if warm moist air is circulated over the dammed, cold air. Thus, while perhaps not as dramatic as cyclones, anticyclones have their own unique and interesting features and impacts.

Introduction

This article will consider the role of the human in forecasting for middle or high latitudes where the weather is dominated by synoptic-scale disturbances.

The role of the human in forecasting the weather, be it for the next few hours or for up to a week ahead, has changed enormously over the last 30 years. Long gone are the days when the forecaster relied on empirical rules and some very basic dynamics to predict the next day's sea-level pressure pattern and hence the weather. For some time this part of the task has been carried out for the forecaster, and, with increasing accuracy, by numerical weather prediction (NWP) models. For forecasts up to 36 h ahead serious errors in the predicted surface pressure and upper wind patterns are rare. One important advantage that human forecasters still have over the numerical model is their ability to interpret cloud or moisture patterns from satellites in terms of weather systems. Although the forecaster cannot normally expect to 'beat' the computer at predicting the pressure pattern over a large area, there is still scope for local adjustments based on an assessment of the accuracy of the initial conditions upon which the numerical forecast is based. NWP models are less accurate when predicting the actual weather elements such as precipitation amount and type, cloud amounts, fog, etc. The forecaster's role has increasingly become that of interpreting and refining raw NWP products, especially in terms of weather elements. However, there are still a few occasions when numerical guidance can go seriously wrong and the forecaster must continually monitor the NWP output for signs of this and be prepared to modify the whole forecast if necessary.

There are many different roles required of forecasters, depending on who their customers are. They may be providing central guidance on the synoptic-scale evolution to other (local) forecasters, or providing forecasts for the general public (most often via the media), to the military, to civil aviation or to other commercial customers and on a variety of time scales. One common aspect of all these roles is timeliness. A weather forecast, particularly a short-range forecast, is a very perishable commodity, and even forecasts for several days ahead may be subject to adjustment after 12 h, when the next set of NWP products are produced. It is normally 2–3 h after data time before NWP products become available to the forecaster and there is often a further chain of processing and briefing before the forecast reaches the customer.

As NWP models continue to improve and mesoscale and single-site models enable more accurate prediction of local weather, the ability of the forecaster to add value to the numerical guidance will continue to decrease, at least on average. The forecaster's role for most of the time will become that of interpretation. However, there will still be rare occasions when the NWP models produce large errors. Although not making much impact on skill scores such as rms errors of mean

sea-level pressure (MSLP), these are likely to be associated with rapidly developing systems that may produce life-threatening extreme weather events, and it is in recognizing these occasions that forecasters will continue to prove their worth.

Central Guidance

Most national weather services of developed countries have a central guidance center whose role is to provide an interpretation and assessment of the latest NWP products and to issue warnings of any expected severe weather likely to be a threat to life or property. In many cases this is extended to guidance on the actual weather details expected so as to ensure that all forecasts issued by different offices of the national weather service are consistent. Because of the time taken to disseminate the guidance, this is usually for the period from about 6 h ahead to perhaps 5–7 days ahead.

Analysis

The first step is for the forecaster to analyze the current situation. Up until a few years ago this would normally have involved hand drawing of surface-pressure maps and upper air height contours. Nowadays computer-drawn 'first guess' charts (usually a 3 or 6 h forecast from a previous model integration) are nearly always close enough to reality for the forecaster to use these along with surface and upper air observations and satellite and radar imagery to recognize the dominant weather systems and processes at the current time. Most NWP models are global in extent, but for short-period forecasts, the forecaster will normally restrict his or her interest to the forecast region and an area upstream, though this may be fairly large (typically the whole of the North Atlantic for European forecasters and most of the North Pacific for those in the United States or Canada). Using conceptual models of these processes and systems, the forecaster then compares satellite and radar imagery and surface and upper air observations with the computer-drawn charts in order to assess the accuracy of the NWP first-guess fields. If there is a discrepancy between the NWP field and the observations, the forecaster will be alerted to a possible problem with the subsequent forecast. In most cases, if the difference is small, it will be corrected by the numerical analysis scheme and the new analysis $t + 0$ h field of the next model run will be a closer fit to the observations. However, if the difference between the observations and the background field is large, the observations may be rejected by the quality control procedures. In some centers such as the UK Met Office, it is possible for the forecaster to intervene to assist the quality control scheme make the correct decisions, to add weight to crucial observations in the assimilation scheme, and even to invent 'bogus' data where satellite or radar imagery suggest the

Figure 1 An example of a VDU display used to check NWP background field with observations and satellite imagery, in this case $t + 6$ h background field (blue contours) and $t + 0$ analysis (red) MSLP compared with surface observations and infrared satellite image over part of the central North Pacific. Important observations are arrowed. An observation from a drifting buoy (a) has a pressure of 997.0 hPa, nearly 13 hPa lower than the $t + 6$ background. The satellite image supports the idea of a more rapidly deepening low than suggested by the NWP field, but the ship observation (c) to the south looks unrealistically low, though the 30 knot (15 m s^{-1}) northwesterly wind supports the idea of a deeper low to the north. A pressure of 1008.0 hPa looks more likely than 1000.8; mistakes in coding frequently lead to this sort of error. To help the assimilation scheme a bogus observation (b) of 1002 hPa and a 40 knot (21 m s^{-1}) southerly wind has been inserted to the southeast of where the low center was estimated to be. As a result, the $t + 0$ NWP background pressure is a much better fit to the real and bogus observations and more in line with the forecaster's interpretation of the satellite imagery. Reproduced by permission of the Met Office.

NWP background is in error, but where there are no real observations in the area to correct this (see [Figure 1](#) for an example).

Diagnostics

Actual weather elements such as low cloud, fog, surface temperature, and some details of the precipitation, particularly showers, are less well forecast by NWP models than the basic pressure patterns. In order to be able to add value to the raw forecast in these areas the forecaster has to understand the dynamics of the large-scale environment in which the smaller-scale processes are embedded and the way in which the different scale processes interact. Forecasters have access to many diagnostic fields from the NWP models to help them in this task.

As well as surface-pressure maps and upper air contour charts, most commonly used are model relative humidity (as a proxy for cloud) for comparison with satellite imagery, and vorticity, vorticity advection ([Figure 2\(a\)](#)), thickness (a measure of the mean temperature between two levels in the atmosphere), and thickness advection, at various heights, to monitor the two most important aspects of large-scale flow. Wind strength ([Figure 2\(b\)](#)) or wind vectors or barbs are also useful in delineating model jet cores that can be compared with

satellite imagery. Jet cores are often apparent on infrared images as a linear contrast between bright areas of cold high cloud on the warm side of the jet and dry areas of subsided air on the cold side. These features are even more apparent in water vapor images. In differentiating between moist and dry regions of the middle troposphere, these images give information about the atmosphere in cloud-free regions and, through the associated changes in humidity, can indicate ascending and descending-motion associated with developing weather systems before this becomes apparent in other imagery.

Since potential vorticity (PV) has become available as a diagnostic from most NWP models, the strong relationship between water vapor imagery and the distribution of potential vorticity is becoming increasingly used as a tool to check the initial conditions and early stages of a forecast. Dark (dry) areas in the image are associated with high PV in the upper troposphere, while in dynamically active regions, particularly when cyclogenesis is taking place, contours of PV on a quasi-horizontal surface such as a pressure surface or isentropic surface curve anticyclonically over areas of ascent and developing cloud. One problem is picking a suitable surface on which to display the PV, as the area of interest is usually just below the tropopause and the associated pressure and potential temperature will vary with the season, current weather situation, and geographical location. Using the fact that PV increases sharply across the tropopause from around 1×10^{-6}

Figure 2 Examples of model diagnostics used to interpret and understand NWP output. (a) 500 hPa geopotential height contours and absolute vorticity (colors). The forecaster can quickly see where areas of large vorticity advection contribute to ascending and descending motion in the model. (b) 250 hPa geopotential height contours and wind strength (colors). Regions of maximum wind strength (jets) can be compared with indications of jet axes from satellite imagery and important dynamical regions at the entrances and exits to jets and their relative strengths quickly assessed. Images courtesy of the NOAA-CIRES Climate Diagnostic Center, Boulder, CO, USA from their website at <http://www.cdc.noaa.gov/>.

$\text{m}^2 \text{s}^{-1} \text{K kg}^{-1}$ (1 PV unit; PVU) to around 6 PVU in the lower stratosphere the problem can be avoided by plotting the height of a PV surface (usually 2 or 1.5 PVU) that is always close to the tropopause. An example is shown in Figure 3.

On some occasions the relationship between the PV and water vapor imagery can be confused or misleading, particularly in the very early stages of cyclone development. If the development is initially taking place in the low to middle troposphere, the image may show the pattern of ascent and descent before it influences the PV distribution at higher levels. However, another diagnostic, so-called ‘pseudo-imagery’, is becoming available to the forecaster to cope with these problems. The radiance at the top of the atmosphere in the water vapor channel is computed from the numerical model values of

temperatures and humidity and can be displayed either as an image or as contours of brightness for comparison with the real imagery. An example is shown in Figure 4. The comparison of the model PV and the real image (Figure 4(a)) shows a possible problem south-west of Portugal where the numerical model high PV is associated with low radiance in the water vapor image, but the pseudo-imagery (Figure 4(b)) also shows low radiance in this area, confirming that this is due to convective cloud penetrating into the otherwise dry upper troposphere. However, near the center of the image, to the south-west of the Azores, a small PV maximum also corresponds to a region of low radiance in the real image, but in this case the dry, dark area in the pseudo-image extends south to coincide with the PV maximum, suggesting a small error in the model in this area.

The pseudo-image gives a much closer comparison with the actual image, but still has to be used with caution and is best used in conjunction with the PV comparison. Apparent discrepancies between the two images may be due only to poor model simulation of the relative humidity, which may be unimportant in the subsequent developments. On the other hand, a close fit can also be misleading, as many NWP models assimilate water vapor radiances. Any adjustment to the NWP radiance is mostly through the humidity, so it is possible that this may mask an underlying problem with the dynamics.

Interpretation

Most global models will distinguish between and display different types and phases of precipitation, i.e., steady rain or snow from large-scale ascent and showers due to local convection. However, it is still necessary to refine the NWP output in these areas. For example, in most models, showers cannot be advected from their source region and therefore stop abruptly and unrealistically at windward coasts in winter as the air transfers from over the warm sea to over cold land. The extent to which showers penetrate inland will depend not only on local orography, not fully resolved by the numerical model, but also on the large-scale vertical motion. An important aspect of the precipitation in winter is the boundary between, rain, snow, or freezing rain (ice storms). There is a very fine balance between these different types of precipitation when the low level temperature is close to 0°C , depending on the initial vertical profiles of temperature and humidity, and the balance between thermal advection and the cooling of the air by evaporating or melting precipitation, which in turn will depend on the precipitation rate. Any of these physical processes may be inadequately parameterized, but the correct forecast of the type of precipitation is crucial in issuing timely warnings of severe weather. The forecaster must use his or her experience and knowledge of any weaknesses in the NWP models to try to add value to the forecast.

Although NWP models indicate the possibility of strong winds and heavy showers, the forecaster still has to distinguish those occasions with the potential for severe weather, such as violent thunderstorms, tornadoes, hail, and downslope winds, which are not directly forecast by numerical models, and issue advanced warnings. In regions where such severe weather is common, short-period detailed forecasts are issued locally using specialized models, radar, and other forecast aids.

Figure 3 An example of a water vapor image for part of North America overlaid with contours of the height of the PV = 2 PVU surface (red) and wind strength on the surface (blue). The strong gradient of PV = 2 height at the foot of the figure and maximum wind speed corresponds to the edge of the bright area showing that the model jet is correctly positioned while the minimum in PV = 2 height just to the rear (north) of the dark area over the south-east of the Great Lakes shows that the cold trough (area of high upper level PV) in the model is also correctly positioned – reassuring for the forecaster as in the subsequent forecast these two features interact to form an intense depression over the Atlantic Ocean. Image and model fields from the French ARPEGE model supplied by Météo-France Forecast Laboratory.

Correction

When comparing model fields over the first few hours of a forecast with observations and satellite and radar imagery, the forecaster often finds small discrepancies such as not enough or too much rain in the NWP output, fronts or rainbands too fast or slow, or depressions not quite deep enough and hence winds not strong enough. The forecaster can then apply appropriate adjustments to the NWP forecast, assuming that these errors persist through the forecast period or decay or grow in a simple manner. This technique is effective up to 24 h or perhaps 36 h ahead. The adjustments are usually made in terms of written or verbal guidance or by the adjustment of single time forecast pressure charts, but techniques are becoming available to adjust electronically the NWP fields in a dynamically consistent manner at all time frames before the output is disseminated to other users.

Very rarely the NWP initial conditions may be so seriously in error that the forecaster has to disregard the model guidance and use his or her own synoptic and dynamic knowledge to make a new forecast. **Figure 5** shows a satellite image for the North Atlantic on 23 December 1997. Conceptual models of cyclogenesis suggest that the cloud area (a) indicates a rapidly developing depression, whereas the NWP field showed only a very weak circulation (b). Although not a bad fit to the available surface observations, the analysis and subsequent

forecast were considered completely inadequate, a theory confirmed by the development of the cloud area in the next 2–3 h. The forecaster overrode the NWP model to forecast a deep depression just west of Ireland 24 h later (**Figure 6**). The manual forecast depression was 16 hPa deeper than the unmodified forecast and only 3 hPa higher than the actual depth, though marginally displaced, and enabled the forecaster to give timely warning of damaging winds over parts of Ireland and the UK.

Medium Range

Even after 24 h, different models sometimes show significant differences in detail of weather patterns. An example is shown in **Figure 7**. Although the forecast pressure pattern (**Figure 7(a)**) is hardly different in the two models, apart from a deeper trough over Tennessee, there are large differences in the predicted rainfall over the west coast of the United States, over Mexico, and particularly over the south-eastern states (**Figure 7(b)**). The forecaster has to use his knowledge of the strengths and weaknesses of the two models to help decide which is more likely to be correct. Beyond about 36–48 h ahead, errors in the initial conditions or those due to imperfections in the numerical models have grown such that forecasts from different initial times or by different forecast centers normally

Figure 4 (a) An example of a water vapor image overlain with contours of PV (blue, interval 0.7 PVU) and geopotential height (yellow, interval 120 m) on the 300 hPa surface. begin to differ. It is no longer possible to predict with confidence details or exact timings of weather events, though the general evolution and type of weather systems likely to be experienced can usually be predicted out to 4 or 5 days, and sometimes beyond this.

At this range it is no longer possible to extrapolate errors in the initial conditions, nor is it possible to beat the models at a dynamical forecast, but there is still a role for the human forecaster. Most large forecast centers exchange raw NWP output with one or two other centers for use as backup, so that the forecaster can usually compare output from two to three or more different model integrations for their region of interest in the same format on screen. In addition to this, the output from many global models is available via the Internet, so that the forecaster may have available as many as 10 different models to choose from. At the same time, several centers around the world are addressing the problem of the uncertainty in the initial conditions and the subsequent error growth by running ensembles of forecast with slightly different initial conditions

Figure 5 Infrared satellite image over part of the North Atlantic for 1200 UTC 23 December 1997 overlaid with first guess NWP $t + 6$ h MSLP field (contours every 4 hPa). The area of cloud (a) indicates a rapidly developing depression, whereas the model has only a weak depression (b). Reproduced by permission of the Met Office.

in an attempt to cover all the possible evolutions of the real atmosphere.

In spite of the inherent uncertainty, many customers still require a categorical forecast. The mean of the ensemble of different forecasts is on average more skillful, at least in rms terms, than an individual forecast because it averages out the less predictable smaller-scale features, but by its nature is very bland and does not give a good indication of the actual weather. The forecaster must use his or her judgment and synoptic experience to select most likely evolution or 'blend' elements from different models, the so called deterministic forecast.

However, it makes more sense to couch forecasts at this range in terms of probabilities. Even with the deterministic forecast, this is done to some extent by the confidence placed in the forecast. It is important to try and convey this in public service forecasts. If a large, slow-moving anticyclone covers the region, the forecaster may be almost 100% confident of dry weather, but in a more changeable spell of weather, even though the most probable forecast is for a transient ridge of high pressure to bring a dry day, possible errors in timing could mean that there is still a 50% chance of rain. Having decided on the most likely evolution, it is important to convey the degree of uncertainty associated with this, particularly when issuing guidance to other forecasters so that they can couch the forecast for their customers in suitable terms.

For forecasts of point probability, normally expressed in terms of the likelihood of a threshold being exceeded, such as wind speed of gale force or more, the ensemble forecast can give a direct estimate. However, ensembles based on a single model, in spite of perturbations to the physics within the model as well as to the initial conditions, still do not cover the whole spread of possible outcomes. An ensemble of different models such as accessed by the forecaster via the Internet often has greater spread (though it is not uncommon for all models to agree but still differ from reality). There is also still the problem that the models may not accurately predict the

Figure 6 Infrared satellite image for area over and west of UK for 1200 UTC 24 December 1997 overlaid with 24 h numerical forecast MSLP (blue, dashed contours) and 24 h forecast modified by the forecaster (red contours), contour interval 8 hPa in each case. The satellite image clearly suggests a deep depression and surface observations confirmed that the modified forecast, of a depression of 976 hPa was much more accurate than the NWP version (990 hPa). Reproduced by permission of the Met Office.

weather elements, in spite of having the correct pressure pattern. There is therefore still scope for the forecaster to add value to probability forecasts of individual weather elements, though time will necessarily limit this to a few crucial parameters at only a few geographical locations. A logical conclusion is then for these corrections to the ensemble forecast to be applied to an appropriate degree at surrounding locations.

Specialist Forecasts

Aviation

Forecasts for aviation again rely very heavily on NWP guidance. They can be divided roughly into three types of forecast.

- *High-level significant weather forecasts.* These are forecasts of conditions near the tropopause where jet airliners fly.
- *Low-level significant weather forecasts.* These forecast conditions up to around 10 000 ft (3048 m), used by 'general' aviation, e.g., private pilots, small local airlines, military aircraft, couriers, etc.,
- *Terminal airfield forecasts (TAFs).* These are forecasts of surface wind and weather elements at specific airfields.

Upper-level significant weather charts are produced centrally by centers designated by the international Civil Aviation Authority to display jet streams, the level of the tropopause, and any high-level aviation hazards, in an agreed format, and are usually valid for fixed times 18–24 h ahead and are updated every 6 h. An example is shown in [Figure 8](#). At normal flight levels, the weather does not often present a serious hazard to modern airliners. The main concerns for airlines are the temperature

and wind speed, which will affect fuel consumption. These are generally forecast very well by NWP models and most companies take direct NWP forecasts of winds in digital form for use in flight planning. Only very rarely will a forecaster see the need to correct the NWP winds. The main hazards at these levels are thunderstorms and clear-air turbulence, though it is also the responsibility of weather services to track and warn of volcanic ash.

Areas of thunderstorm activity are reasonably well forecast by the NWP models, but it is still necessary for the forecaster to check and sometimes correct details such as cloud top height. Forecasters must also use their experience to decide whether thunderstorms are likely to be isolated, in which case they are not considered a hazard, or embedded in other cloud layers so that they cannot be easily detected, or difficult to avoid due to their spacing or due to being in a line. Occasionally the models may misplace or miss areas of thunderstorms altogether, especially in the tropics, where a series of recent satellite images may be a better guide to activity over the next 24 h.

Clear-air turbulence occurs in areas of strong wind shear, normally around jet streams. It is not associated with cloud and therefore cannot be detected in advance, and can be sufficiently violent to cause injury or even death to passengers or aircrew if not restrained by seat belts. However, it is a very intermittent phenomenon and impossible to forecast precisely at present. NWP models provide an indication of regions of strong vertical or horizontal shear where turbulence is likely to occur, but this is a necessary rather than a sufficient condition. Forecasters can add value by using conceptual models of the type of airflow most likely to lead to actual severe turbulence to refine the forecast. Areas where a risk of moderate or severe turbulence is

Figure 7 (a) Comparison of 24 h forecasts from two NCEP models, valid 0600 UTC 22 February 2001. Solid contours are of sea-level pressure, every 4 hPa. The colours represent the thickness layer between the 1000 and 500 hPa, a measure of the mean temperature of the lower troposphere. (b) Comparison of the forecast rainfall accumulations for the same forecasts as in (a) for the 12 h up to 0600 UTC. Images provided by the NOAA-CIRES Climate Diagnostic Center, Boulder, CO, USA from their website at <http://www.cdc.noaa.gov/>.

expected are marked on the significant weather charts along with the range of heights over which the hazard is expected to extend. However, most of the time, aircraft flying through these areas experience no serious problems. For this reason pilots encountering severe turbulence make an immediate report, which is relayed to the forecaster, who then issues a more definite forecast in the form of a SIGMET. This is a text forecast, which is disseminated with maximum priority to all aviation users, so that any following aircraft may take avoiding action or at least ensure seat belts are in use. If a forecaster is sufficiently convinced of a high risk of severe turbulence he or she may issue a SIGMET without any actual aircraft reports. SIGMETs are also issued when there is very high confidence in the forecast of other hazards such as embedded thunderstorms, line squalls, and severe low-level turbulence, or when these events are observed.

Low-level significant weather forecasts are also mostly produced centrally, but nationally rather than regionally, and are normally valid for shorter periods, typically up to 9–12 h ahead, though planning forecasts are produced from some centers for up to 36 h ahead. As well as the thunderstorms and

turbulence (though in this case normally low-level turbulence due to strongwinds flowing over the Earth's surface), low cloud (especially where it covers hills) and icing are the main forecast parameters. Although NWP provides a framework of the positions of frontal zones, areas of convection, etc., parameters such as the amounts and base of low cloud, visibility, and the likelihood of icing are not well forecast numerically, and the forecaster relies more on experience and extrapolation of present conditions, subject to any changes in the large-scale conditions indicated by the NWP models.

The third type of forecast, the TAF, is normally valid for 9 h ahead, although at major airports, forecasts of up to 24 h ahead are provided to give airlines an idea of likely risk of long-haul flights being diverted. Forecast parameters are wind speed and direction, cloud amount and height of base and visibility, plus any weather conditions that may be a hazard, such as thunderstorms, hail, snow, freezing rain, and mist or fog, though the latter are also implied by the visibility. These forecasts have traditionally been produced locally on site by forecasters who have a great deal of experience of the peculiarities of the particular airfield, and are based largely on extrapolation of

Figure 8 Part of a high-level aviation significant weather chart, produced by World Area Forecast Center Washington, valid 1800 UTC 19 June 2001. Surface fronts are shown by conventional symbols, and jet streams (wind speed >80 knot) by the magenta-colored arrows, with the maximum wind strengths in red (each barb represents 10 knot, and the solid triangles 50 knot). Yellow dashed lines outline areas of forecast moderate or severe clear air turbulence. The height range (in hundreds of feet) over which the turbulence may occur is indicated by the associated text. The green scalloped areas denote areas of significant thunderstorm activity, with details of flight levels affected in the associated boxes. Provided by the NOAA-CIRES Climate Diagnostic Center, Boulder, CO, USA from their website at <http://www.cdc.noaa.gov/>. ($1 \text{ knot} = 5.14444 \times 10^{-1} \text{ m s}^{-1}$.)

local or upstream conditions after allowance for diurnal changes, and effects of local topography and an idea of the synoptic-scale development. This is still true in many cases, especially at military airfields, but improved local detail and better estimation of actual weather parameters from mesoscale numerical models has meant that it is becoming possible for these forecasts also to be produced centrally with a single forecaster responsible for the TAFs for a dozen or more airfields.

Marine Forecasts

Detailed forecasts of surface wind speed and direction, visibility, and sea state are normally provided for up to 24–36 h ahead. For the high seas, well away from land, numerical models provide a good estimate of all but visibility, though it may be necessary for the forecaster to make some adjustments in accordance with any central guidance on the perceived accuracy of the latest NWP forecast. Visibility is estimated, within broad limits, from knowledge of the source of the air mass, the air temperature relative to the sea surface temperature (will the air be cooled by the sea to form mist or fog?), and consideration of recent ship reports in the same air mass.

Coastal forecasts rely slightly more on local knowledge and interpretation of numerical output around complex coastlines, as numerical models are not always detailed enough to

represent these effects on the wind speed and direction or sea state, nor do they adequately represent small-scale changes in sea surface temperature likely to have an important impact on mist or fog formation.

Local Forecasts

The local forecaster has to consider the numerical model output and any corrections that may be made to this in the central guidance, then adjust the forecast for any small-scale effects due to local topography that may not be fully resolved by the numerical model. He or she will be concerned with the combination of these effects on weather parameters such as rainfall rate, rain–snow boundaries, cloud amount and sunshine, temperature, fog, and how they vary across the region. The forecaster will also have to understand the synoptic-scale dynamical processes taking place in order to make sensible adjustments to the numerical forecast.

Accurate forecasts of temperature at individual sites are crucial for forecasts of fog, frost, and snow in winter, and for showers, and in particular thunderstorms, in summer. The central guidance may indicate that these weather elements are to be expected over a broad area, but the local forecaster must estimate the risk at individual locations. There are several semi-empirical models available to forecasters to estimate diurnal

Figure 9 Radiosonde ascent from Denver, Colorado, at 1200 UTC 29 April 2001. The vertical scale is logarithmic in pressure and approximates to height. The diagonal pale blue lines are temperature in °C, every 10°. The solid red line shows the temperature profile and the green line the profile of humidity mixing ratio. The blue line represents the temperature curve of a parcel rising from the surface without any mixing with its environment and with an initial temperature of 20°C. The surface pressure is around 830 hPa because the station is over 5000 ft (1640 m) above sea level. Environmental curve provided by the NOAA-CIRES Climate Diagnostic Center, Boulder, CO, USA from their website at <http://www.cdc.noaa.gov/>. The parcel ascent curve was added by the author.

temperature changes that can be used to check and refine NWP output. The forecaster will use profiles of temperature and humidity from local radiosonde ascents, plotted on an aerological diagram, to diagnose the type and height of any cloud layers and assess the likely developments due to diurnal changes in temperature. The forecaster will then compare the basic profile and his or her analysis with those from the numerical model, and in particular assess the potential for shower or thunderstorm development. An example is shown in Figure 9. The solid red line shows the temperature profile and the green line the humidity mixing ratio, or dew point temperature. The temperature at the surface is colder than the air just above as this is a night time profile, but as the temperature at the surface rises during the day the temperature will become warmer than that just above the surface and the air will begin to rise. Unsaturated air will cool as it rises, following the red dashed lines. At the same time the humidity mixing ratio will remain constant and the dew point will therefore follow the yellow dashed lines. In the example the surface temperature must reach 20°C before the air can rise sufficiently to reach the condensation level and form convective (cumulus) clouds. The temperature will fall along the blue line until the air parcel becomes saturated at the point a, after which it will cool more slowly due to the release of latent heat as the water condenses in the cloud. In an unmixed parcel the temperature would now follow the dashed green lines. The continuing blue line therefore gives the maximum height to which a parcel could rise. In practice, except in the core of a large

cloud, mixing with drier air outside the cloud will lead to re-evaporation of some of the cloud water and the parcel will cool more quickly and air parcels would be unlikely to rise beyond the point b, as they would then be cooler than the surrounding air. However, the forecaster would have to consider if the air at this level is likely to be cooled by the large scale motion or if local conditions could lead to warmer or moister conditions near the surface. A small change may allow the air to rise all the way to the tropopause causing the formation of heavy showers or thunderstorms (unlikely though in the example, as the surrounding air is very dry and mixing would cool the parcel back towards the environment temperature). The forecaster would check his or her prediction of showers with the NWP output. If no showers were indicated, the forecaster would need to ask why. Does the model surface temperature reach the required value? Does the model represent the observed sounding adequately in its initial conditions? The formation or otherwise of even severe storms may hinge on the detail of a shallow layer of higher temperature, which may not be resolved by the numerical model.

Introduction

Weather maps provide an irreplaceable, succinct summary of a wide variety of atmospheric phenomena and characteristics. They are a critically important working tool for the operational and research meteorologist, both of whom become very familiar with ways of illustrating features of interest that can be immediately appreciated by their peers. In a sense, weather satellite and weather radar images are maps of aspects of the weather. However, this section will not deal with remotely sensed fields, but with maps that portray weather-related features at the surface or in the upper air.

History

Surface Weather

Weather maps are nothing new. Synoptic meteorology is concerned with understanding relatively large-scale weather-producing disturbances like frontal depressions, tropical cyclones, and anticyclones – features that have a horizontal scale of many hundreds to a few thousand kilometers, and a lifetime counted in days rather than hours.

The earliest instrumental weather records began soon after the invention of the thermometer and barometer. Robert Hooke's manuscript from 1664, kept at the Royal Society in

Figure 1 Halley's map of trade winds and monsoons. From Halley, E., 1686. An historical account of the trade winds, and monsoons, observable in the seas between and near the tropicks, with an attempt to assign the physical cause of the said winds. *Philosophical Transactions of the Royal Society* 16: 153–168.

London, summarized the keeping of such early observations. He did in fact appreciate the value of a network of weather observations, although it would be many decades before that became a reality. The late seventeenth and early eighteenth centuries saw the simultaneous use and gradual expansion of thermometry and barometry to many western European countries and America. This was also the age of sail, with many navies plying the Atlantic Ocean and other oceans.

It was the English natural philosopher Edmond Halley (1656–1742) who published the very first map to depict an

atmospheric variable, in the *Philosophical Transactions of the Royal Society* of 1686. This was strictly a climate map, to illustrate the mean surface winds over the tropical regions of the Atlantic and Indian Oceans (**Figure 1**).

The stimulus for producing the first weather map proper lies with a letter written to the *Annalen der Physik* in 1816 by Professor Heinrich W. Brandes of Breslau University (now Wrocław University). He suggested that a daily surface weather map could and should be produced for part of the period from 1781 to 1792: this was the era of the Meteorological Society of the Palatinate, based in Mannheim, Germany. The society fostered the science during this period when observations were taken three times a day, collected from 39 people across 18 mainly European countries.

It appears however, that this significant pioneering work was never summarized in map form – until Brandes's proposal that led him to plot 365 maps for 1783. These maps have never been found however; they were not a part of his article on 1783's weather in the *Annalen* of 1819. However, there are published reconstructions of his weather map for 6 March 1783 that illustrate both the simultaneous distribution of the departure of pressure from average and surface winds (**Figure 2**).

In 1831, the American James P. Espy (1785–1860) organized a committee from his base in the Franklin Institute in Philadelphia to collect weather data: in 1834 the Joint Committee on Meteorology was formed by the Franklin Institute and American Philosophical Society with Espy as chairman. The first American weather map based on widespread observations appeared in an 1837 issue of the *Journal of the Franklin Institute* (**Figure 3**).

The prime problem with all these early endeavors however was that the maps could be drawn only after the event. They did, though, offer meteorologists at least some insight into the scale of synoptic features, how pressure and wind appeared to be related, and how pressure features moved and evolved.

Figure 3 Espy's weather map for 20 June 1836. From Espy, J.P., 1841. *The Philosophy of Storms*. Boston: Charles C. Little and James Brown.

Register map indicating conditions of the atmosphere on the same day in several parts of Great Britain from observations collected at the great exhibition for 9 a.m. 24th Sept 1851 by the electric telegraph company

Figure 4 Daily weather map, Great Exhibition, London, 1851. Met Office Library.

The full utility of the weather map had to wait for a truly momentous event for the world as a whole, when Samuel Morse connected Washington and Baltimore by electric telegraph in 1844. This brilliant development paved the way for the ultimate 'live' mapping of weather observations and so to producing up-to-the-minute weather maps. By 1860, the Smithsonian Institution in Washington, DC had organized the electronic transmission and display of current weather reports from some 45 companies in the United States. The details were presented on a large map on public display in the institution.

In Europe, some few years earlier, the world's first same-day weather maps were being offered to the public gaze at the Great Exhibition of 1851. This was held in the Crystal Palace, situated at that time in Hyde Park in London. From 8 August to 11 October the public could purchase a copy of the day's weather map for the British Isles (**Figure 4**).

From about 1863, the Daily Weather Map Company of the Strand, London, offered monthly subscriptions to maps of

British and Irish weather (**Figure 5**). Across the Channel, Jean Joseph Le Verrier (1811–77), director of the Paris Observatory, founded a daily weather summary for mainly France in 1858. From September 1863, the bulletin of the Paris Observatory included a daily weather map.

On 1 April 1875, the London newspaper *The Times* initiated the presentation of a daily weather map to a much wider public. It published a chart of 8 a.m.'s weather for the previous day over the British Isles and parts of continental Europe that included plotted details of temperature, wind direction, 'weather', sea state, and analyzed isobars.

The first regularly published daily weather map in the United States appeared in the New York *Daily Graphic* on 9 May 1879, although this initiative lasted only a few years. By the final decade of that century however, many daily papers around the world had incorporated a weather map.

The gradual increase in the number of nations publishing 'government' weather maps led to the desirability of some sort of internationally accepted standard way to depict or symbolize

Figure 5 Daily Weather Map Company's map accompanying their promotional material (c. 1863).

the broad range of surface observations. Although such a standard was accepted at the International Meteorological Congress in Vienna in 1873, it was not to be globally accepted for some decades.

By 1891 at least, some 18 countries – mainly in Europe – were publishing government-service synoptic weather maps. As the surface weather network expanded, so did the area covered by weather maps. From 1 January 1914, the US Weather Bureau published surface weather maps for the entire Northern Hemisphere routinely. After World War I, many of the world's

weather services were producing their own analyses on this scale.

In postwar Norway a group of brilliant scientists led by Vilhelm Bjerknes (1862–1951), now known as the 'Bergen School', worked on the analysis of weather changes associated with the passage of traveling synoptic-scale disturbances in that region. The group refined some of the work from the previous century in which the notion of pulses of warm and cold air in the extratropics had been discussed. They developed the concept of warm and cold fronts, and the more

Figure 6 Vertical cross-sections and plan view of an open wave frontal depression. Reproduced with permission from Bjerknes, J., Solberg, H., 1922 Life cycle of cyclones and the polar front theory of atmospheric circulation. Geofisike Publikationer 3(1): 3–18.

general structure of the commonplace mobile frontal cyclones.

Jacob Bjerknes (1897–1975) and Halvor Solberg (1895–1974) published a highly significant ‘map’ of such a system in 1922 (Figure 6).

Another member of the school, Tor Bergeron (1891–1977), proposed the term ‘occlusion’ and the currently used symbols for the three types of surface fronts. In addition he suggested the used of slightly different symbols for upper fronts.

This exceptional work on the structure and evolution of extratropical frontal cyclones – and the location and representation of such fronts on surface weather maps – formed the basis for how all the world’s weather services located these critically important features. The methods have moved on, so that in the UK Met Office, for example, objective schemes are utilized for the automatic positioning of fronts – or at least for providing useful guidance to the analyst.

Upper-Air Weather

During the 1890s, Frank Bigelow of the then US Weather Bureau composed wind charts for three levels covering the contiguous United States. He did so by analyzing surface anemometer data along with lower and upper cloud drift observations supplied from 140 telegraphic stations. The cloud information was taken to represent the circulation at 3500 and 10 000 feet (1067 and 3048 m), so that early ‘upper air analyses’ were made available before the year 1900. It was as early as 1903 that Bigelow began the publication of daily barometric pressure charts for the two constant levels above and for that of mean sea level (Figure 7).

A supplement to these observations was provided by the use of kites. These sensed pressure, temperature, humidity, and wind speed up to a height of some 3 km but were replaced in

Figure 7 Barometric pressure analyses for mean sea level, 3500 feet (1067 m), and 10 000 feet (3038 m). Reproduced with permission from Bigelow, F.H., 1903 IV. The mechanism of countercurrents of different temperatures in cyclones and anticyclones. Monthly Weather Review 31: 26–29.

the 1930s by pilot balloons. Such balloons were tracked optically to enable mapping of wind direction and speed at a variety of heights – so long as cloud didn’t mask the observer’s view.

This significant problem was overcome during the next two decades with the advent and gradual spread of radio-tracked balloons known as radiosondes. They transmitted ‘live’ data to their ground launch station from their pressure, temperature, and humidity sensors, and were tracked by radar to derive wind information. Today there are some 600 to 650 unevenly scattered radiosonde stations globally that report pressure, wind, temperature, and humidity twice daily.

Modern Surface Weather Maps

It is true to say that the way in which the surface weather features like highs, lows, and fronts are represented on today's analysis charts is not very different from those of the interwar years of the twentieth century. There has been an extension of the symbolism to include frontogenesis and frontolysis, and greater appreciation by forecasters of the variety of, for example, cold fronts. The advent of weather satellites and radars has aided our knowledge of the variety of frontal structure – and this appreciation has led to the need to inform forecasters of the differences, for example, between 'ana' and 'split' cold fronts. The latter would be ideally represented on a weather map by a surface cold front symbol and a leading upper cold (humidity) front symbol.

The use of supercomputers in weather analysis and forecasting has opened up a massive array of surface weather representations that are mapped automatically. The 'classic' map of mean sea-level isobars is still produced as a global analysis. **Figure 8** exemplifies these for the larger part of the Northern and Southern Hemispheres, from the European Centre for Medium-Range Weather Forecasts (ECMWF). Larger-scale maps illustrate predictions of the mean sea-level pressure field, as well as a derived field. **Figure 9** is a map of the prediction of mean sea-level pressure, valid at 12 UTC at the end of a 48 hour forecast, and of total precipitation during the last of the two days (00 to 24 UTC). The isobars thus provide a snapshot of likely conditions at one instant, while the precipitation patterns are expressions of the rain, drizzle, or snow that is forecast to fall from disturbances over the whole 24-h period in question.

As an extra aid to operational meteorologists, it is possible also to indicate the likelihood that the 24-h precipitation total will exceed some critical value. **Figure 10** highlights three such criteria: the probability (5%, 35%, 65%, and 95%) that the total fall over 24 h will exceed 1 mm, 5 mm, and 10 mm. Similarly, **Figure 11** illustrates the same probability values for the 10 m wind speed to exceed 10 m s^{-1} and 15 m s^{-1} . The latter falls just inside the category of 'gale'.

Modern Upper-Air Maps

As with weather maps for the surface, the range of charts available for the representation of upper-air features has increased dramatically over the last decade or so.

There are still the 'traditional' synoptic maps. At ECMWF, for example, the predicted height field for the 500 hPa surface is charted as it has been for many decades (**Figure 12**). The contemporaneous thermal field at 850 hPa illustrates the large-scale waves of relatively warm and cold air in the lower troposphere. As with some surface phenomena, the model can provide indications of the extent of, for example, predicted 850 hPa anomalies that are greater than $\pm 4 \text{ K}$ and $\pm 8 \text{ K}$ (**Figure 13**).

An innovative synoptic map produced by ECMWF is that of the predicted cloud cover for low, medium, and high levels. Such maps are provided in daily time steps, valid at 1200 UTC, and in essence give a broad indication of what a satellite image might look like at each of these times. They act as another indicator for the forecaster – of whether a particular weather-producing system is composed of deep cloud or shallow cloud, for instance (**Figure 14**).

Figure 10 Probability of predicted 24-h precipitation exceeding (a) 1 mm, (b) 5 mm, and (c) 10 mm. Reproduced with permission from the European Centre for Medium-Range Weather Forecasts.

Figure 11 Probability of predicted 24-h 10 m wind speeds exceeding (a) 10 m s^{-1} and (b) 15 m s^{-1} . Reproduced with permission from the European Centre for Medium-Range Weather Forecasts.

Figure 12 Predicted 850 hPa temperature (deg C) and 500 hPa height (dm). Reproduced with permission from the European Centre for Medium-Range Weather Forecasts.

Figure 13 Probability of predicted 850 hPa temperature anomalies: (a) less than -8 K, (b) less than -4 K, (c) greater than 4 K, (d) greater than 8 K. Reproduced with permission from the European Centre for Medium-Range Weather Forecasts.

Figure 14 Predicted cloud cover: low (yellow), medium (red), and high (blue). Reproduced with permission from the European Centre for Medium-Range Weather Forecasts.

It is not possible to illustrate the truly enormous range of weather maps available to today's forecaster. The fact is that some charts have stayed the same over many decades, and for good reason. The mean sea-level isobaric and frontal analysis has stood the test of time: there have been extensions of the symbolism used as our knowledge of the variety of fronts has improved. There has not been the need to abandon these representations for something better. Similarly, the standard upper-air isobaric height analyses are still among the working charts that operational meteorologists use.

What is different nowadays, however, is that a whole host of analysed or forecast fields that are a particular forecaster's favorite can be called up at the press of a button. What might be chosen can depend on the situation at hand, and must of course be used profitably within the strict time confines of the operational forecast cycle.

This is the critical change to the production and utility of weather maps today. It is that they can be provided automatically, rapidly, for a larger range of basic or derived fields, and

can be overlain with satellite images, for example. This "richness" can not only aid the forecaster's day-to-day operations but also gradually improve their knowledge and understanding of the phenomena to hand.

Cyclogenesis

GJ Hakim, University of Washington, Seattle, WA, USA

Introduction

Cyclones are associated with horizontal winds circulating in the same sense as the local vertical component of planetary rotation; this circulation is clockwise in the Southern Hemisphere and counterclockwise in the Northern. Cyclogenesis is defined as the formation and amplification of cyclones. The emphasis here will be on cyclogenesis in the extratropical latitudes, near the westerly jet streams; i.e., poleward of about 30° latitude. Extratropical cyclones (hereafter, cyclones) are responsible for organizing significant short-term weather, such as cloud and precipitation patterns. Cyclones are also crucial components of the Earth's climate system because they regulate the pole–Equator temperature contrast, stabilize the density stratification, and maintain the westerly winds in midlatitudes against frictional dissipation.

Cyclones have horizontal length scales on the order of about 500–2500 km and may span the depth of the troposphere (~ 10 km). When compared with an undisturbed environment, cyclones are associated with relatively lower pressure (~ -10 hPa), circulating winds (~ 10 m s $^{-1}$), relatively warm air (~ 10 K), and rising air (~ 10 cm s $^{-1}$). The wind field is nearly in geostrophic balance, so that the wind flows parallel to lines of constant pressure and the wind speed is proportional to the magnitude of the horizontal pressure gradient (the spacing between the pressure contours). Cyclones also represent locally large values of other quantities that are derived from the wind, temperature, and pressure fields, such as: kinetic energy, vorticity, and potential vorticity. Vorticity provides a local measure for the rotation rate of the wind. Potential vorticity is approximately the product of vorticity and a measure of density stratification; it gives the vorticity that a sample of air would have (i.e., potentially) if taken to a reference latitude and rearranged adiabatically to a reference density stratification. Potential vorticity (PV) plays a central role in the modern understanding of cyclogenesis, and is reviewed below under 'Dynamics of Cyclone Development'.

Basic Facts and Definitions

Cyclones can be categorized with regard to the thermal structure of the atmosphere near their centers. Warm-core cyclones are strongest near the Earth's surface (hereafter, surface) and weaken with height. Cold-core cyclones are strongest near the tropopause and weaken toward lower height. Extratropical cyclones can be viewed as an amalgam of warm- and cold-core cyclones, with a warm cyclonic circulation at the surface and a cold cyclonic circulation near the tropopause. These circulations are not aligned vertically, but are displaced laterally by hundreds of kilometers in developing cyclones. This configuration allows the disturbance to extract energy from the jet stream.

Since the atmosphere near cyclones is in, to very good approximation, hydrostatic balance (vertical pressure-gradient

forces balance gravitational forces), cyclogenesis implies that there is a net loss of mass from an imaginary column of air over the surface cyclone. This loss of mass accounts for the drop in surface pressure, and is associated with net divergence of air from the air column. Frictional drag at the surface disrupts geostrophic balance, so that the near-surface winds converge toward low pressure. Therefore we can conclude that upper-level divergence must be important for cyclogenesis. Moreover, since the atmosphere is nearly incompressible on horizontal length scales typical of cyclones, lower-level convergence and upper-level divergence are linked by mass continuity to upward air motion in the troposphere.

It is reasonable to assume the existence of a constant-pressure surface, P_0 , in the stratosphere that is undisturbed by the cyclone. Decreasing surface pressure during cyclogenesis implies that the thickness between a constant-pressure surface near the ground and P_0 increases; i.e., the layer is warming with time. Falling pressure in the cyclone center also implies that the magnitude of the pressure difference between the cyclone center and the surrounding environment, and therefore the geostrophic wind speed, also increases with time.

These deductions on cyclogenesis, based on geostrophic and hydrostatic balance, are self-consistent; however, they do not reveal why or how these changes come about. Further analysis of the time variation of individual quantities, such as surface pressure, are incomplete, since, importantly, all quantities are dynamically related. An analogy for this difficulty considers analyzing a moving automobile to discover the process responsible for locomotion. One might consider the decreasing mass of gasoline in the fuel tank as a crucial aspect for locomotion, rather than as a diagnostic indicator for the action of the internal combustion engine. Fortunately, the dynamics of cyclogenesis can be concisely described in terms of a single quantity that implicitly incorporates all others: the potential vorticity. Before considering the dynamics of cyclones, it will prove useful to document the evolving structure of a typical cyclone.

Structure of Developing Extratropical Cyclones

Cyclones originate on zones of horizontal temperature contrast that are located in the vicinity of the extratropical jet streams (Figure 1(a)); occasionally, the temperature contrast is concentrated in a narrow frontal zone. The nascent cyclone appears as a region of low pressure downwind (following upper-level winds) from a preexisting upper-level disturbance called a short-wave trough. This horizontal displacement between the surface cyclone and the short-wave trough is required for the disturbance to extract energy from the jet stream. Viewed on a level surface, the upper-level disturbance appears as a trough of low pressure or, equivalently (as shown in Figure 1), as a trough of low geopotential height (or, simply, height) on a constant pressure surface. These features are

Figure 1 Schematic illustration of a developing extratropical cyclone. Heavy solid lines give contours of 500 hPa geopotential height; thin solid lines give contours of 1000 hPa geopotential height; dashed lines give contours of 500–1000 hPa thickness, which is proportional to the mean temperature in the 500–1000 hPa layer. Fronts are denoted by heavy solid lines with filled half-circles and triangles. (a) shows the early stages of development, (b) shows the mature stage, and (c) shows the occluded stage. Reproduced with permission from Palmén E and Newton CW (1969) *Atmospheric Circulation Systems: Their Structure and Physical Interpretation*. New York: Academic Press.

referred to as short-wave troughs because their 1000–2000 km horizontal length scale compares with greater than 5000 km for so-called long-wave troughs. The short-wave trough is actually a manifestation of a downward displacement of the tropopause, with large values of stratospheric PV extending to lower altitude. (PV is typically much smaller in the troposphere due to less-stable density stratification.) A region of large wind speed often can be found near the trough when the flow is not strongly curved – this feature is called a jet streak, since it represents a local region of strong winds within the jet stream.

As the cyclone continues to deepen, warm air advances poleward and cold air advances Equatorward – the leading edge of these advancing air masses marks the location of surface warm and cold fronts, respectively (Figure 1(b)). Warm, moist air flowing poleward rises at the warm front up and over the colder, denser, air at low levels, producing a widespread region of precipitation. Cold, dense air associated with the cold front displaces warmer air at the cold front, producing a narrow band of precipitation.

Eventually, the cyclone separates from the surface warm front and migrates toward the cold air forming an occluded front. The deepening rate of the cyclone slows during this

time, and eventually ceases when the surface cyclone and upper-level trough are nearly coincident in the vertical (Figure 1(c)). Viewed from an energy perspective, cyclogenesis represents a conversion of potential energy associated with horizontal temperature contrasts into kinetic energy. Cyclogenesis is a thermally direct circulation with warm air rising as it flows poleward, and cold air sinking as it flows Equatorward. A net result of this process is a reduction in the pole–Equator temperature contrast and more-stable density stratification (dense air underlying less-dense air). A typical duration for the cyclogenesis process depicted in Figure 1 ranges from about 12 to about 60 h.

Dynamics of Cyclone Development

Cyclogenesis is associated with the development of disturbances in the fields of wind, temperature, pressure, and density. Deriving a comprehensive dynamical understanding of cyclogenesis in terms of the temporal variation of each of these quantities is laborious and redundant, since these quantities are dynamically related. This difficulty is overcome through

two simplifications that engender concise and deep insight: approximating the dynamical equations (using the quasigeostrophic approximations) and casting the resulting equations in terms of a single variable, the potential vorticity (PV).

Quasigeostrophic Dynamics

The observations that cyclones are nearly in geostrophic and hydrostatic balance motivates adopting quasi-geostrophic (QG) dynamics, which represent a simplification of the actual governing equations. The important result for our purposes concerns the fact that the entire QG system can be formulated in terms of PV, assuming adiabatic and frictionless conditions:

$$D_g Q = 0 \quad [1]$$

where D_g is the time rate of change following the geostrophic motion. Q is the PV, which in the QG case is the sum of geostrophic vorticity and a measure of static stability, except at the surface where Q is proportional to temperature. Cyclonic Q has the same sign as the local vertical component of planetary rotation – positive in the Northern Hemisphere and negative in the Southern. At the surface, cyclonic Q is associated with relatively warm air.

Note that eqn [1] is a simplified version of a more general relation that applies to the unapproximated governing equations. Equation [1] indicates that PV is conserved (i.e., unchanging) following the geostrophic motion, and that QG dynamics are simply described by the rearrangement of PV. From this perspective, all other quantities (pressure, temperature, etc.) can be viewed as subservient to PV in that, it should be emphasized, they *evolve so as to conserve PV*. Since Q cannot be measured directly, it may seem less gratifying than quantities such as pressure and temperature. However, one may imagine that a discovery of ‘PV meters’ prior to barometers and thermometers would perhaps have rendered pressure and temperature as foreign and contrived quantities!

A second important fact about PV is that all other variables can be recovered from it through a process called inversion:

$$I(Q) \rightarrow \vec{V}_g, w, P, T \quad [2]$$

where $\vec{V}_g$ is the geostrophic wind, w the vertical component of the wind, P pressure, and T temperature. Inversion I can be performed analytically for simple distributions of Q , and otherwise can be performed numerically; the details are unimportant here. A useful illustration of inversion applies to a small sphere of cyclonic Q , which can be viewed as an elemental building block from which arbitrarily complex flow patterns can be constructed. Application of I to this small sphere shows that relatively low pressure is found in and around the sphere, a cyclonic geostrophic wind field is found around the sphere, and relatively warm (cold) air is found above (below) the sphere. These patterns have largest magnitude near the sphere, and weaken with distance in all directions. The fact that the fields of wind, temperature, etc., extend far from the small sphere is fundamental to understanding how atmospheric disturbances interact.

More complicated flow patterns can be recovered from this simple example by summing the contributions from PV in all

locations. This ‘superposition principle’ allows one to rigorously decompose the atmosphere into essential components, and to diagnose dynamical interactions among the components. For example, the following section shows how the dynamics of cyclogenesis are given by an interaction between the tropopause PV disturbance and the surface cyclone.

A Potential Vorticity Schematic of Cyclogenesis

Figure 2 gives idealized schematics of the dynamics of cyclogenesis in vertical cross-section and plan view. In the vertical cross-section view, a depression of the tropopause gives a local blob of cyclonic PV on level surfaces (Figure 2(a); note the plus sign). This PV disturbance is associated with the 500 hPa short-wave trough noted in Figure 1. There is low pressure near the PV disturbance and a region of cold air below it in accordance with the simple example given previously. (Note that the upward bulge in the isentropic surface is due to the fact that potential temperature increases with height in a stably stratified atmosphere.) Low pressure at the surface is located near relatively warm air downwind of the upper-level low pressure (cf. Figure 1). In contrast, the temperature disturbances tilt downwind with height; this

Figure 2 Schematic illustration of potential vorticity concepts applied to cyclogenesis. (a) East-west vertical section showing the tropopause (thick solid line), the surface (thick cross-hatched line), a lower-tropospheric isentropic surface (dashed line), and the air circulations required to conserve potential vorticity for the typical case where westerly winds are increasing from the surface to the tropopause. Regions of relatively warm and cold air are given by W and C, respectively, and regions of relatively low and high pressure are given by L and H, respectively. (b) Horizontal plan view showing the surface isotherms (solid lines), surface wind associated with the upper-level PV disturbance (dashed lines with arrows), and surface wind associated with the surface cyclone (solid lines with arrows). In both (a) and (b), the plus sign shows the location of the PV disturbance due to the lowered tropopause.

configuration is necessary to achieve a conversion of potential to kinetic energy.

The arrows in [Figure 2](#) show the air circulations necessary to conserve PV for the typical case where westerly winds are increasing from the surface to the tropopause. Air converges into the cyclone near the surface and then rises toward the tropopause where it diverges. Conversely, on the upwind side of the PV disturbance, air converges near the tropopause and then sinks toward the surface where it diverges near the surface anticyclone. Note that a reverse circulation exists in the lower stratosphere, and is only hinted at in [Figure 2](#). Downwind of the PV disturbance, these circulations raise (lower) the isentropic surfaces below (above) the level of the disturbance in order to conserve PV as the westerly winds transport the PV blob eastward.

In plan view, the horizontal wind field due to the upper-level PV disturbance extends downward to the surface and contributes to the poleward (Equatorward) transport of warm (cold) air near the surface cyclone (anticyclone) ([Figure 2\(b\)](#)); note that this illustration applies to the Northern Hemisphere). These transport patterns amplify the surface cyclone by warming the center of the cyclone (or, an increase in surface PV, since relatively warm air at the surface represents cyclonic PV). In contrast, the horizontal wind field due to the surface cyclone produces temperature transport patterns that are out of phase with respect to the surface cyclone. These transport patterns are responsible for propagating the disturbance toward the east. Similar interpretations apply near the tropopause, assuming that the PV increases horizontally toward the pole, as is typical. Near the tropopause, winds attributable to the surface cyclone amplify the upper-level PV disturbance, and winds attributable to the upper-level PV disturbance propagate the disturbance toward the west, relative to the westerly winds.

Finally, we note that diabatic heating can be accounted for within the PV framework. Diabatic heating contributes to the generation of the PV disturbances (non-conservation of PV, or a source term on the right-hand side of eqn [1]), with a cyclonic PV disturbance below, and an anticyclonic PV disturbance above, a region of maximum warming. Since the cyclonic PV disturbance below the heating is in close proximity to the surface, it contributes to a reduction in the cyclone surface pressure and enhances the winds at the cyclone center.

Theory of Cyclogenesis

The leading theory of cyclogenesis, baroclinic instability, posits that the westerly jet streams in the extratropics are unstable to infinitesimal disturbances that grow exponentially in time. The most rapidly growing disturbances in this theory are waves in the horizontal direction, and they have maximum amplitude at the tropopause and surface. For typical extratropical conditions, these disturbances have horizontal wavelengths around 4000 km, propagate at about 15 m s^{-1} , and double their amplitude over slightly less than one day. These characteristics are qualitatively in accord with observations, although the growth rate may appear to be too slow to account for the development of observed cyclones from infinitesimal perturbations over a 48 h time period.

Objections to Baroclinic Instability Theory

When surface friction is introduced to the baroclinic instability theory, the already small disturbance growth rates become even smaller. In fact, some research suggests that the jet streams are stable to baroclinic instability; in other words, the growing disturbances do not exist. Another objection points to the fact that observed cyclogenesis events proceed from preexisting large-amplitude disturbances on the tropopause, not infinitesimal noise. Moreover, cyclogenesis events tend to be highly localized in the horizontal, not plane waves as in baroclinic instability theory, and the vertical structure of observed cyclones tends to change with time as compared with the fixed structure of an unstable disturbance.

A second theory for cyclogenesis attempts to account for the noted deficiencies by employing disturbances having structures and growth rates that change in time. Although these disturbances decay over long time intervals, they can produce very large growth over short time intervals. The theory for optimal perturbations formalizes the search for disturbances that have the largest growth over short time intervals, such as 48 h. An amazing result of this theory is that even in cases where friction is sufficiently strong to stabilize a particular jet stream to baroclinic instability, optimal perturbations may still exhibit large growth over the time interval characteristic of observed cyclogenesis. Although the rapid growth and time-varying structure of optimal perturbations make them appealing candidates to explain observed cyclogenesis, there is at present no evidence to support such claims.

Reconciliation of Baroclinic Instability Theory with Observations

Careful examination of observations and the stability properties of observed flows together indicate that baroclinic instability theory can in fact account for observed cyclogenesis, once two factors are taken into consideration. First, observed precursor disturbances tend to be localized in the horizontal direction, which means that a sum of disturbances, rather than a single disturbance, should be considered; the sum allows for a localized disturbance through cancellation of the components away from the local maximum. Second, these localized disturbances have large, not infinitesimal, amplitude (cf. [Figure 1](#) and [Figure 2](#)). An initial disturbance of modest initial amplitude comprising an unstable component can grow over a few doubling times to account for the amplitude of observed disturbances.

It is clear, however, that other factors not emphasized here play a contributing role in cyclogenesis; for some cyclones this role may be essential. For example, diabatic heating appears to contribute positively to cyclogenesis in many cases. Another potentially important process involves the transfer of heat and moisture from the sea surface during oceanic cyclogenesis. The most intense and most rapidly developing cyclones are found over the western North Atlantic and North Pacific oceans, where strong ocean currents maintain regions of large horizontal temperature contrast in the lower troposphere. Another important effect

in these locations is due to cold continental air flowing over relatively warm water, which results in weak static stability. Weak static stability reduces the doubling time for baroclinic instability and may allow greater latent heat release through stronger upward air motion and precipitation. Orographic barriers are also important in initiating or enhancing cyclogenesis, owing to the strong adiabatic warming that occurs in the lee when air flows over the mountains. Cyclones often form in the lee of major mountain barriers and then move downwind.

Another energy source contributing to cyclogenesis involves a transfer of existing energy from upwind disturbances. Since the disturbances propagating along the jet stream are strongly dispersive Rossby waves (phase speeds vary with wavelength, so that a group of waves with similar wavelength does not move at the phase speed), the energy in these disturbances can radiate away from existing disturbances. This energy radiation can contribute to a sequence of cyclogenesis events through a process known as downstream development.

Glossary

Baroclinic interaction This expression is introduced in this article in order to name the main physical mechanism that explains the development of extratropical cyclones. It is useful to distinguish the actual mechanism that couples finite-amplitude vortices within a baroclinic zone from baroclinic instability, which applies to the spontaneous growth of small perturbations within such a zone.

Initiation of a cyclone The expression cyclogenesis is becoming ambiguous, since it does not necessarily applies to the birth of a new cyclone, but is also employed for its growth and amplification. This is acceptable in the perspective of very basic life cycles based on continuous growth under the same physical conditions. The climatological reality is somewhat different and calls for a more precise vocabulary. This article calls the initiation phase of a cyclone life cycle, the first detection of an individual vorticity maximum, that is the initial formation of a new cyclone.

Maturation phase in a cyclone life cycle This article refers to maturation as the 24-h period preceding the maximum amplitude reached by vorticity at the core of a cyclone in the course of its life cycle.

Weather regime This expression is employed in this article in the sense of a quasi-stationary large-scale flow pattern, 'large scale' meaning on the scale of an oceanic basin like the North Atlantic or North Pacific.

Units

In general, SI units are used for contour intervals in particular for vorticity (s^{-1}). The following exceptions can be found:

Geopotential The SI unit for geopotential ϕ is the J kg^{-1} . However, maps of geopotential are rescaled to the so-called dynamic height ϕ/g , where g is a constant conventional value of the acceleration of gravity internationally agreed upon by the World Meteorological Organization ($g = 9.80665 \text{ m s}^{-2}$). The unit of dynamic height employed is denoted mgp for meter geopotential: other symbols may be used.

Potential vorticity A convenient nonconventional unit is employed, the pvu (potential vorticity unit).
 $1 \text{ pvu} = 10^{-6} \text{ K m}^2 \text{ kg}^{-1} \text{ s}^{-1}$.

Wind speed In addition to the SI unit (m s^{-1}), the practical unit knot (kt) is also employed. $1 \text{ kt} = 1852 \text{ m}/3600 \text{ s}$.

Synopsis

This article opens with an example of extratropical cyclone introducing life cycles and a few other key concepts. The next section documents the distribution of cyclones. This is followed by a brief summary of how cyclones have been conceptualized in the past and how some of them can be seen using data with very little preconceived ideas. The main mechanism involved in cyclone development and some recent views on how this mechanism may be implemented in the atmosphere is presented. The article is then completed by looking at cyclones at two opposed scales: first from a small-scale perspective presenting some key cyclone substructures and then from a large-scale one, with some ideas on the feedback of extratropical cyclones on the general circulation.

Introduction

Extratropical cyclones are the ubiquitous sources of weather variability at mid- and high latitudes on the timescale of a day or so. A full day of more or less continued snow or rainfall, with a low dark gray sky overcast with clouds followed by a colder showery spell is a sequence of events generally organized by an extratropical cyclone moving over a given location.

Extratropical cyclones are key actors of the climate of these latitudes, particularly in the autumn and winter. Their presence during the cold seasons means mild air temperature and water supply, albeit unpleasant at the time it happens, especially

when it takes the form of tons of snow. However, their absence often implies spells of extreme temperatures and, if it lasts, it may be the precursor of drought in the warmer seasons.

Extratropical cyclones are also known as storms, gales, and other tempests when they reach extreme intensities. They are, in fact, the main causes of weather-related disruptions and destructions over areas the size of a state or a country at mid- and high latitudes. These result primarily from extreme winds but slow and extended floods are another hindrance. Indeed, if such cyclones show up every other day over the same places for weeks or even months in a row, the water supply turns into major flooding. Along the coasts, storm surges, namely the sea

level reaching unusual heights, also are dangers related to extratropical cyclones. They can drown dikes and the lowlands that it was supposed to protect.

Because of their large impact on navigation and circulation in general, extratropical cyclones have long been the focus of weather forecast and weather understanding. For some time when the first attempts of applying scientific reasoning to weather were undertaken, extratropical and tropical cyclones have been combined into the number one marine and coastal weather forecast problem. However, although their name somehow maintains this confusion within the language, they are quite distinct phenomena. One characteristic they do share, however, seen from the surface, is that the most intense ones seem to happen quite suddenly as a bad surprise. Predicting the occurrence of a midlatitude storm with enough lead time has challenged forecasters for decades if not centuries. About every forecasting technique that has been devised ever since weather forecast is attempted has been applied to storm alert and has failed. It is only very recently that the best global prediction systems seem to have predicted most major events. As will become apparent in the review that follows, everything might be important for achieving such a result. But this may primarily be attributed to unprecedented observation and data assimilation capabilities as well as stepping back from making deterministic predictions. However, the focus of this article is on the observation and the understanding gained from combining observations and theoretical ideas applied to extratropical cyclones. Although the latter are often integral parts of ‘understanding,’ one ambition of this article is to try to keep a link with real world extratropical cyclones as seen in real data.

It begins with an example of extratropical cyclone from which key aspects can be identified, such as life cycles or relevant key fields for representing them. The next section provides some statistical basis to these aspects; it also documents the distribution of cyclones. This is followed by a brief summary of how cyclones have been conceptualized in the past and how some of them can be seen using data with as least as possible preconceived ideas nowadays. It provides a good introduction to reviewing the main mechanism involved in cyclone development and some recent views on how this mechanism may be implemented in the atmosphere. The article is then completed by looking at cyclones at two opposed scales: first from

a small-scale perspective presenting some key cyclone substructures and then from a large-scale one, with some ideas on the feedback of extratropical cyclones on the general circulation.

An Introductory Case Study

Now that we are well into the weather satellite era, the look of an extratropical cyclone seen from outside the Earth is quite familiar: it is a large roughly λ -shaped cloud system, with the upper part of the λ more or less hooking back about a nearly cloud-free area. An example of this organization is shown in [Figure 1](#). One panel displays a large cyclone on the Earth ‘seen from infinity’ over the northeastern Pacific south of the Aleutian Islands. This image has been built by combining three channels of the US NOAA GOES (National Oceanographic and Atmospheric Administration Geostationary Operational Environmental Satellites) west geostationary satellite. Before the satellite era, the field that best gave the idea of the extent of an extratropical cyclone is the mean sea-level pressure. It is shown in the other panel together with an alternative representation of the cloud system, using an angle preserving plane view. In this framework, an extratropical cyclone is a ‘low,’ that is a broadly circular area of lower pressure. These are relatively large-scale views, with various sources of smoothing, partly due to the large size of that particular case. [Figure 2](#) provides some details of the same case, thanks to zooming on a part of it and of making use of a high-resolution instrument on a low-orbiting satellite. There, the main cloud band appears to be filamented in its highest part transversal to its overall orientation. While this band nonetheless remains a continuous cloudy area seen at that level of detail, this is quite different with the multiple forms of organizations that can be seen within or near the center of the system or in its northwestern part, with many individual clouds.

This weather system has been chosen somewhat randomly to a large extent because at that stage, it looked ‘typical,’ typical in particular of the storms that hit the western coast of North America. Its extent and some of its structure is revealed by three different ways. One uses measurements of the radiation emitted by the atmosphere in the infrared band or infrared wavelength, then collected by a radiometer orbiting at the same speed as the

Figure 1 Example of extratropical cyclone in the Northeastern Pacific Ocean. Left: false colors infrared multichannel composition from NOAA GOES west geostationary satellite. Right: analysis from the operational global data assimilation system of Météo-France. Black contours are isobars, interval 4 hPa, thicker reference 1000 hPa. Colored surfaces represent cloudiness derived from explicit cloud water content, combined from 70 levels to three layers (low-level (L), midlevel (M), and high-level (H) clouds). The main colors are given in the figure. The more cloudiness, the lighter the shade, shades correspond to a layer or a combination of these three layers, so that white corresponds to an area overcast by the three overlapping layers. The characteristic cloud system is closely associated with an area of low pressure.

Figure 2 The same extratropical cyclone as observed by the high-resolution visible imager Moderate Resolution Imaging Spectroradiometer (MODIS) from NASA, at about the same time. This image provides details of the different cloud types and their organizations.

Earth, nearly 36 000 km away from it. Another one is, like the human eye, sensitive to radiation reflected by the atmosphere, especially the clouds: the instrument is more like a kind of digital camera that requires an external source of light, here, the Sun. The third representation combines part of these data with many other sources and with a numerical model of the atmosphere: it results from a continuous data assimilation process.

Sources of Data

This leads to presenting briefly what are the various sources of data that can be used to study extratropical cyclones. There are

three main sources of combined, processed informations suitable for dynamical analyses of systems of that scale:

- the products of operational, routine observation, and data assimilation systems. The example case is illustrated using such a source, which is now a mature system processing a very large amount of data.
- the result of dedicated observational programmes or field experiments. This has long been very helpful, even mandatory, because the routine observing system has, for a long time, suffered from many weaknesses and blind spots. To some extent, such programmes remain useful today, thanks to the level of *in situ* data they enable to collect, while the routine network is completely dominated by remotely sensed data. **Figure 3** illustrates such a reasonably recent field project, called the Fronts and Atlantic Storm-Track Experiment (FASTEX). It was ambitiously innovative in that it aimed at tracking cyclones at several times and where they were. Up to then, it had mostly been possible to wait for them at some place, even a wide place. Depending on the programme design, not the same aspects could then be studied.
- both those approaches enable excellent description of some cases, but only a limited number of them. In the case of dedicated observation programmes, there are special efforts to collect significantly more data than the routine network does, but this effort is clearly limited in time. In the case of operational analyses resulting from data assimilation, a large collection of cases is prevented by the lack of homogeneity of the data: such operational systems change quite often, which allows for improving them in many ways. When it comes to ascertain what is 'typical' and what is special, a large, homogeneous set of cases is required. This is provided by reanalyses. Reanalyses are based on the same approach as the first source data assimilation. However, they benefit from two specific features. One is the recovery or reprocessing of past data, some of which was not used in operational analyses. Or, simply, they are observations older than the first operational analysis system. Another

Figure 3 An example of special deployment of observational platforms to document the life cycle of extratropical cyclones, here during the North Atlantic wide FASTEX project in 1997. The balloon symbols mark the location of radiosounding stations. The darker they are colored, the most frequent were the soundings, from 12 hourly to 3 hourly. The ships are also intensive radiosounding locations. Beside the cyclone track, marked 6 hourly by heavy dots, some of the flight tracks are also shown.

feature is that they are performed over rather long periods (half a century, now aiming to cover a century) with the same but recent data assimilation system. This provides both the statistical depth and the homogeneity.

The availability and the growing use of reanalyses to study a number of atmospheric phenomena such as extratropical cyclones from a well organized yet observation-rooted dataset is probably one of the most notable recent progress. Several aspects of cyclones are presented here using several generations of reanalyses.

The data assimilation technique that is behind the description of the example case or behind the most recent reanalysis uses more than 10^6 individual measurements in each 6-h time windows. More than two-thirds of these measurements are satellite derived. Three main sources of data are combined: measurements of many different kinds, now covering the whole globe; a first guess estimate of what the weather is at the time the measurements were made, provided by a model time integration and the previous assimilation window; this embodies the memory of the weather system; and the third source is a mixture of dynamical and statistical constraints, such as an estimate of the uncertainty, which is now changing as the situation evolves. These sources are combined using optimal control theory.

The result of most of these approaches takes the form of collections of four-dimensional (4D) gridded fields. Their most frequent use is for visualization or diagnostic calculations, in the spirit of an essentially observational science. However, more experimental approaches are becoming available as will be shown later. This is made possible because the data organized in this way can also be used for running models, some of them highly realistic.

Life Cycle Description

The cloud and low-pressure system seen in [Figure 1](#) can be recovered at other times, both in the images and in the sequence of analyses. A summary is provided by [Figures 4](#) and [5](#). They are built like [Figure 1](#), with a multichannel infrared image on one column and the clouds and mean sea-level pressure from the assimilations on the other. The first fact to point out is that a cyclone such as this travels and changes shape. [Figure 4](#) begins 500 km south of mainland Japan and continues 4.5 days later with a stormy day at Anchorage, Alaska. It is a distance of more than 7000 km covered at an average speed of roughly 18 m s^{-1} or 35 kt. In terms of intensity measured by pressure deepening, it keeps amplifying throughout this period, reaching a minimum of about 970 hPa, starting at around 1013 hPa. However, this is not a proper measure of the intrinsic intensity of the system because the pressure field also has a strong large-scale component: part of the apparent pressure fall simply results from the system moving northward, where the large-scale pressure is lower. The strongest low-level winds, another indication of intensity related to the horizontal gradient of the pressure field, undergo a different, much more complex history as discussed below. These apparent discrepancies in measures of intensity also are typical. The look of the cloud system, supported by the pressure field, brings, on the other hand, a nontypical aspect of this case: prior to the time of [Figure 1](#), the

system appears to be made up with two systems. Notice that the double-cloud system that can clearly be seen at times 31/03 00UTC and 01/04 00UTC in the images is also well represented by the assimilation fields, in spite of the fact of this event taking place in the middle of the Pacific Ocean. A third system further to the west is also present and vanishes both in images and in assimilation fields.

The underlying representation of the layering of the cloud systems in both series of panels is somewhat different. In the images, there is no signal that can come from below the top of the highest thick (nontransparent) cloud layer. The temperature of this layer is indicative of its height. Combining several channels conveys some idea of the spatial variation of this cloud top height. In the assimilation, cloud cover, here consistent with cloud water content, redistributed from 70 to 3 layers has been used. The color scheme explicitly represents overlapping layers. Hence, white in the images indicates the coldest clouds in all channels, meaning high continuous clouds: this information is conceptually turned into meaning that this is also the location of the deepest, snow-providing clouds. In the assimilation, deep clouds are actually indicated.

The main low is called hereafter Low M, while the other system is denoted Low P, for precursor low because it is the first to form. From this first representation, it could be said that these two systems merge into one. This is only a first impression.

Surface pressure and cloud cover are familiar representations of an extratropical cyclones but more information is needed to start develop an understanding of how all this works. [Figure 6](#) proposes some of this information. Instead of pressure, the low-level part of the systems is now represented by the 850 hPa relative vorticity. This level is located at a height of about 1.5 km. It is the bottom of a troposphere less turbulent than the boundary layer located below. Relative vorticity is the curl of horizontal wind. It is large in the presence of cyclonic rotation induced by the wind field, or in the presence of large cyclonic horizontal shear. The latter is better seen in a high-resolution vorticity field, while the former is most apparent, with smaller amplitudes, in a low-resolution vorticity field. At the times shown in [Figure 6](#), the two systems M and P are closely coupled, possibly with at least another transient one in between on 30/03 12UTC. While the amplitude of Low P increases, that of Low M decreases.

The other fields, like pressure in previous figures, combine the signature of the systems of interest with a larger scale component more representative of their environment. Such a one is the maximum wind field near the tropopause, the surface that can be considered, very loosely, as the top of the weather-active atmosphere. The representation used follows the World Meteorological Organization (WMO) conventions: the direction is the direction from which the wind blows, the speed is given by the barbs and triangles: a full barb is 10 kt ($\sim 5 \text{ m s}^{-1}$); a triangle is 50 kt ($\sim 26 \text{ m s}^{-1}$). The wind is plotted only above a minimum speed, so that provides the shape of the areas of the strongest upper-level wind. It is clear from these figures that the evolution of the cyclones is closely related to the confined maximum of upper-level wind. Because it is of limited meridional extension, this characteristic organization of the wind field is called a jet stream. Notice also that the jet stream changes significantly in the zonal direction: at the

Figure 4 Left column: multichannel compositions from two geostationary satellites over the Pacific Ocean. The channels used are near-infrared ($\sim 0.6 \mu\text{m}$), thermal infrared ($\sim 10.8 \mu\text{m}$), and mid-infrared ($\sim 3.8 \mu\text{m}$). The main cloud systems reaching the highest levels appear white, except in the first image from which the near-infrared is absent because it is a night scene. Images are from the Japan Meteorological Agency Multi-Functional Transport Satellite (MTSAT). Right column: analysis from the operational global data assimilation system of Météo-France, as in Figure 1. Images are centered on the same extratropical cyclones, while maps show them windowed on a single projection. This highlights that extratropical cyclones travel at the same time as they form and grow. In this case, they appear south of Japan and begin to cross the Pacific Ocean.

first time shown (30/03 12UTC), the systems are just west of an area of expansion of the jet, a confluence or entrance zone. More to the east, there is an area of minimum expansion and speed.

The description of the upper level also includes one representation of the tropopause surface, namely its height. Here, the tropopause is given a dynamical representation: it is a surface of constant potential vorticity, instead of being given solely by the change of the vertical temperature gradient. Potential vorticity combines this gradient with others resulting in a quasi-conserved property. The height of the tropopause can roughly be read like a mean sea-level pressure map is. It can be seen that the tropopause is higher on the warm side of the jet stream than on the cold side: the jet stream is also the location of a kind of meridional step of the tropopause height. It can also be seen that the tropopause is especially low on the cold side of the jet, just

west of the systems of interest. Indeed, cyclonelike anomalies can be noted in the height field aloft Low P.

To document further the atmosphere at low levels, contours of moist potential temperature θ'_w are displayed. Like the tropopause height, this field has a strong zonally large-scale meridional gradient. It is enough to keep in mind that there is warm and moist air on the equatorward side and cold and relatively dry air on the poleward side. Values are not given because there are several definitions of moist potential temperature, some giving very different but not relevant magnitudes: magnitudes can be considered to be somewhat arbitrary. Away from the systems of interest, this gradient appears to be located on the warm side of the jet stream aloft. This field is also closely related to the systems of interest: contours are moving into the jet area with them, the gradients also appear to be modified in their vicinity.

Figure 5 Continuation of **Figure 4**, showing the systems apparently merging into the single cyclone of **Figure 4**, while closing the northeastern Pacific and the coasts of Alaska and Canada. The first image is from MTSAT while the others are from NOAA GOES west satellite.

The picture is completed by the distribution of relative humidity at 700 hPa (about 3 km altitude). This can be seen as an indication of a single layer cloud cover. Nearly saturated areas are also places where precipitation processes are active. This field can also be read as a smoothed version of the vertical velocity. There is a distinct maximum accompanying the systems of interest, but note also the bandlike structure that runs along the warm side of the jet stream.

Figure 7 shows two later times. It appears that between time 31/03 12UTC and 01/04 12UTC, Low M has intensified but it decays somewhat later on. It continues to move northeastward. In fact, and quite remarkably, it has moved from the warm to the cold side of the jet stream in an area where the jet weakens. The upper-level tropopause height anomaly catches up with Low M, later to find itself equatorward of the low-level system at the same time as being heavily stretched along the poleward jet side. The gradients of low-level moist potential temperature have become very strong in some places, but this also is transient and reduces at the last time shown. Finally, Low P, seen through its vorticity signature, does not merge into Low M.

Instead, it seems to orbit cyclonically around it while decaying rapidly and crossing the jet stream from cold to warm side.

After having described the systems and some aspects of their environment when they grow most and reach a mature stage, consider now the conditions at the time when some early sign of their formation can be seen, starting with Low M (**Figure 8**). It may be worth noticing that both these systems, as well-defined low-level vorticity maxima or surface pressure minima, cannot be traced back indefinitely: they both have a genesis or initiation time. The previously described fields are used here as well, although organized slightly differently. The upper-level jet structure is reinforced by showing contours of its speed: the presence of confluence aloft the area of formation of Low M is quite clear. But the picture is dominated by the presence of Low P, which at that time is already quite developed. It strongly influences the low-level flow, as can be seen in both the moist potential temperature contours and the 850 hPa wind field. Actually, the low-level flow, where Low M forms, is quasi normal to the θ'_w contours. At the same location, there is a relative humidity maximum and ascent. A further noticeable

Figure 6 An alternative representation of the life cycles of Low P and Low M, more suitable for a dynamical analysis of their evolution. Instead of mean sea-level pressure, the low-level part of the structure is shown by the positive part of the 850 hPa relative vorticity field (for legibility) (purple thin contours, in units of f , the Coriolis parameter, with yellow to red shading for the systems of interest, using the color scale given in the first panel). The flow at the tropopause is shown by the upper-level wind, concentrated in a westerly jet stream, shown at 200 hPa by the blue barbs drawn when the wind speed is larger than 60 m s^{-1} . This enables to view the flow directions as well as areas of confluence and diffluence, as the major one in the central Pacific. This sequence corresponds to the development phase of the life cycle of Low M. The left column displays another key upper-air field, the tropopause height, defined as the geopotential height of the surface of constant potential vorticity with a value of 1.5 pvu or $1.5 \times 10^{-6} \text{ km}^2 \text{ kg}^{-1} \text{ s}^{-1}$ (brown contours, interval 1000 mgp, thicker contour 10 000 mgp). The right column concentrates on the lower troposphere, with the 850 hPa moist potential temperature (dark red contours, interval 2 K) and the 700 hPa relative humidity (green shading, color scale in the top right panel). All fields are from the Météo-France global data assimilation system.

Figure 7 Same as Figure 6 but for the mature phase of Low M.

Figure 8 The situation at the time when the incipient Low M can first be hinted in the 850 hPa vorticity field. Left panel: mid- and upper-troposphere fields, superimposed on the low-level vorticity (purple contours, yellow to red shading with scale as in Figure 6). The fields are the 700 hPa relative humidity as in Figure 6, the geopotential height of the tropopause (brown contours, -2000 m anomalies highlighted with orange shading) and the 200 hPa wind field above 60 m s^{-1} (blue barbs and white contours every 10 m s^{-1} above 30 m s^{-1}) also as in Figure 6. Right panel: 850 hPa relative vorticity is related to mean sea-level pressure (black contours, interval 4 hPa, thicker reference 1000 hPa), 850 hPa moist potential temperature (dark red contours, interval 2 K), and 850 hPa wind field (light blue barbs).

feature is the upper-level anomaly of tropopause height, with a well-defined minimum slightly to the west of Low P. Note that the vorticity maximum indicated as the incipient Low M is not the strongest one in the area. This specific attribution may indeed be disputed: it remains that these conditions are creating a number of new systems that, in a way or another, will turn into Low M.

The conditions of formation of Low P share one or two aspects with those of the formation of Low M: the presence of confluence of the jet stream aloft as well as the preexistence of an upper-level cyclonic anomaly seen here in the tropopause height (Figure 9). Unlike the previous situation, the low level appears to be quite unorganized aside from the meridional gradient of moist potential temperature. One sign of this is the lack of connections between surface pressure and vorticity, unlike what was seen at later stages. Moist and ascending areas can be related to the jet (present along the warm side) or to the upper-air anomaly (on its eastward side) but not where Low P begins to form. In short, Low P as a low-level system is a new one, but it seems to have a precursor itself, in the form of an upper-level only system.

Case Study Summary

This real world extratropical cyclone case provides a number of significant facts that will be gathered together here.

Consider first the weather system itself, or rather the two systems Lows P and M. They are well materialized by fields such

as relative vorticity or by the finite-amplitude anomalies in fields such as surface pressure, various temperatures, wind, and of course clouds. One way to summarize their evolution is to plot the maximum vorticity amplitude as a function of time (Figure 10). Both systems have a genesis time in the sense that they can be tracked back up to a certain time before which they cannot be identified any more. Low P undergoes a nearly continuous growth phase that lasts for about 18 h. This is followed by quasi-continuous decay, to the point this system, as a vorticity maximum accompanied by anomalies in other fields, vanishes. It takes about 3 days. Initiation or genesis precedes growth to a mature stage then decay to an end also called cyclolysis. This sequence of events, called a life cycle, seems quite close to the ideal situation most often considered in theoretical views: a single, continuous growth phase follows the first appearance of the system. When this growth phase ends, it is followed by continuous although possibly slow decay. There is, however, a huge difference with the ideal life cycle: the important influence Low P and Low M had on one another.

Low M offers a somewhat different profile. Low M starts with an initial, very strong impulse growth during 12 h like Low P. However, this is interrupted for the next 12-h period. Then a new growth phase begins, less rapid but lasting about 24 h, leading to its peak amplitude. During the next 24 h, it loses quite a lot of intensity. A new, third, slow growth phase takes place. The end of this system is not included in the time slot of this study, and in fact, is not easy to define. This is what

Figure 9 Same as Figure 8, but showing the situation at the time the incipient Low P can first be detected in the 850 hPa vorticity field.

Figure 10 Time evolution of the amplitude of Low P and Low M measured by the maximum relative vorticity at 850 hPa.

is called a complex life cycle which actually is quite frequent, as the FASTEX programme mentioned above particularly pointed out. The fact that there are several successive phases of growth is also apparent in other fields, although their beginning and end might seem a bit different.

In vorticity and some other fields, it is quite easy to identify the systems on the vertical in the lower half of the troposphere and somewhat higher. Their signature reaches the upper troposphere in clouds and for Low M, in the wind field, in the form a secondary, transient maximum sometimes called the outflow jet. When looking at the tropopause, however, it is not really possible to spot a structure with a one to one correspondence with Low P and another one with Low M. What can be seen, however, in their close vicinity is indeed a finite-amplitude anomaly that can be tracked as well. But very much like the end of Low M is beyond the time slot considered, both the beginning and the end of this upper-air anomaly happened elsewhere at other times. In particular, this anomaly exists before the low-level systems do. For this reason, the upper-air anomaly can be, must be considered to be an independent system, although like Low P and Low M, there may be some interactions.

This is more apparent when considering the respective tracks of these three structures, as in [Figure 11](#). This figure also summarizes the kind of environment within which these life cycles took place. Quite crudely, this environment is obtained by averaging a number of fields over the period considered: this is a simple way to bring out some key aspects of the large-scale flow. More rigorous time filtering techniques are applied to obtain the research results shown later on. The trajectories, and therefore the life cycles are closely related to the jet stream, which is also an area of stronger meridional gradient of moist potential temperature in the troposphere. The upper-level anomaly and Low P remained on the cold, poleward side of the large-scale jet stream. As this figure shows particularly well, Low M, on the other hand, started on the warm side of the jet and then crossed it. It then continued to move toward Alaska remaining on the poleward side. The crudeness of the way employed to display some characteristics of the environment is probably responsible for the extension of the jet northeastward

from Central Pacific to North America: this is more likely to be the trace of the jet outflow of the then mature Low M.

It is of interest to pay attention to the positions of the lows at several key phases of their life cycles. This figure confirms that both geneses took place while the large-scale jet accelerates. It also shows that the first growth phase of Low M ends while it reaches the longitude of the jet maximum. The second growth phase, on the other hand, corresponds to Low M crossing the jet and also reaching the diffluence area east of the core. Finally, during the growth phases of Low P and the first two of Low M, the upper-level system is located to their west or northwest.

[Figure 12](#) concludes this first description of the key features of the life cycle of extratropical cyclones by focusing on the growth phase of Low M that led it to its mature stage. Maps are provided 12 hourly and, most important, they are kept centered on Low M maximum vorticity, in order to better see the relative positions of the other features as it amplifies. The pressure falls by about 20 hPa in 24 h: this is a quite rapid deepening and another measure of development. The jet outflow is clearly visible in the last panel at least as a secondary maximum at the east of the low. The position of the upper-level anomaly is indicated by highlighting areas where the tropopause is more than 2 km down into the troposphere: it is right above Low P, northwest and west of Low M.

Some of these facts are specific of these cases and rather unusual. But some others are really characteristic of extratropical cyclones. Prior to review what sense is currently made of some of the features seen in this section, their representativeness needs to be documented.

Overview of the Global Distribution of Cyclones

The reanalyses that have been produced these past years are invaluable when it comes to shape what is a 'typical' extratropical cyclone in its 'typical' environment. As explained above, reanalyses are collections of consistent time series of gridded fields, a form that enables many new possibilities with respect to working directly on raw data or even on operational datasets. Very large homogeneous samples are available

Figure 11 Summary of the life cycles of Low P and Low M through their trajectories relative to the mean westerly flow during their lifetime, representative of their large-scale environment. Locations are shown every 6 h. Red circles and line: Low M trajectory. Purple circles and line: Low P trajectory. When these systems can be seen as closed lows in the pressure field, circles are contoured in black. When the detection is not fully definite, a dashed line is employed and the circles have lighter color: this is particularly true for the very first circle of each trajectory. The 850 hPa vorticity field directly related to the systems is shown at four times (purple contours, yellow to red shading, see Figure 6 for the color scale). The mean 200 hPa wind speed is in the background, white contours and blue shading, interval 10 m s^{-1} above 30 m s^{-1} , color scale in the figure. The series of orange circles tracks the minimum tropopause height that can be followed during the same period. Thin colored lines link positions at the same time, but this link does not imply necessarily an actual physical connection.

Figure 12 The main growth phase of Low M shown in a kind of system-relative frame of reference. Namely, each panel is centered on the 850 hPa vorticity maximum of Low M and oriented so that the large-scale flow and baroclinity is oriented from left to right. Fields are 850 hPa relative vorticity (purple contours and yellow to red shading as in Figure 6), mean sea-level pressure (black contours as in Figure 1), tropopause geopotential height (brown contours with orange highlighted low height anomaly as in Figure 8), and 200 hPa wind speed (white contours and blue shading, interval 10 m s^{-1} above 30 m s^{-1} , color scale shown in Figure 11).

through reanalyses, complex computations may be performed on them. A further novelty has been introduced soon after the reanalyses. Synoptic meteorology concepts or objects, such as an extratropical cyclone, a front or a jet streak have begun to receive definitions amenable to algorithmic, and therefore automated, identification in a given set of maps at a given time. Then, comparing successive maps, these structures can be tracked.

Previously, analysis fields were used as gridded times series. Various purely statistical approaches have been applied to them, including time filtering, spatial correlation structures of time filtered fields and the like. In this case, there is no actual meteorological 'object': they are implicitly represented by the choice of a characteristic time period. On the other hand, when studies were undertaken specifically on such 'objects,' most of the work had to be done by eye and hand. As a result, the

samples studied are quite small. Of course, both approaches have provided useful, indeed, essential results. But reanalyses enable to remove the drawbacks of both approaches and allow to reach a further level of description.

One popular reanalysis is known as ERA40 (European centre for medium-range weather forecast (ECMWF), reanalysis covering roughly the last 40 years of the twentieth century). Moving from the North Pacific to the North Atlantic, consider now some results obtained from extracting north-hemispheric fields at a resolution of 1.5° horizontally, 13 pressure levels vertically, every 6 h and for a cold season defined from 15 October to 15 April from 1958 to 2000.

An elementary processing, a simple average of these 42 seasons, provides first a statistically more robust description of what the 'typical' environment of extratropical cyclones is (Figure 13). As in the Pacific case study, a meridionally confined, essentially zonal jet flow dominates the scene. Actually, the oceanic basin is the location of its core, located aloft the eastern coast of the United States and of a vast zone of diffuence. Contours of constant tropopause height or 850 hPa moist potential temperature θ'_w are mostly oriented from west to east, with large values equatorward decreasing poleward. Notice that the stronger the upper-level wind, the larger the meridional gradients of both these fields.

To see that this is indeed the large-scale environment of extratropical cyclones, one of the new approaches enabled by reanalyses has to be employed. It is the automatic tracking of cyclones. To obtain the first results shown here, the following definitions are employed. A cyclone is a well-defined relative vorticity maximum at 850 hPa, that is vorticity is larger than at other grid points within 380 km of the location considered. Certainly only the synoptic scale component of vorticity is needed here. Tracks are constructed first by pairing individual cyclonic events every 6 h. This is performed by applying several criteria taking the wind at the level of the vorticity maximum and the wind at 700 hPa into account and maximizing the likelihood to find the most reasonable association. Once a first

set of trajectories has been obtained, they are also evaluated as a whole by considering some regularity criteria. As this leads to question some of the pairings, the algorithm is iterative and performed backward and forward in time, until the trajectory set does not change any more. One aspect of this algorithm worth pointing out is that it uses very little preconceived ideas. The main one is the use of the 700 hPa wind for estimating a priori a future propagation location based on a kind of wave specific of these environments in a rotating frame called Rossby waves, discussed below. In particular, this technique does not impose any vertical constraint on vorticity. One result from this weakly selective approach is that the number of events found is very large, with many weak and short-lived systems. Some further selection is performed, so that an extratropical cyclone in this paragraph is now a vorticity maximum at low level with a characteristic scale of at least 380 km, a lifetime of at least 24 h and reaching an amplitude of at least $1.5 \times 10^{-4} \text{ s}^{-1}$.

The density of the trajectories of the extratropical cyclone obtained in this way appears in Figure 14. The density of trajectories indicates how many trajectories move over a given point on a 380-km resolution grid during a given reference time, namely an entire cold season. In this approach, one event represented by its full trajectory is counted once per point it moves over: this is different from counting the events themselves. The latter will count the same event several times at a point if it becomes stationary. The displacement speed of the systems can also be computed, and its averaged value at each point is indicated in the figure. The connection of the tracks of extratropical cyclones with the jet flow becomes clearer: they tend to begin close to the mean jet core and continue toward the northeast more on the poleward side of the jet. They also move faster near the jet and on its equatorward side, with velocities of about 30 kt (15.4 m s^{-1}) than on the polewardmost cold side. The selection criteria employed select only significant events, of the same kind as those in the case study. A bit less than 7000 trajectories are included: that is roughly such an event each day of each season somewhere in the area covered by the map in the

Figure 13 Averaged conditions over the North Atlantic Ocean basin derived from the ECMWF ERA40 reanalysis for cold seasons between 15 October and 15 April. Brown contours, the tropopause geopotential height (interval 1000 mgp, thicker reference 10 000 mgp). Dark red contours, 850 hPa moist potential temperature θ'_w (interval 2 K, thicker reference 283.15 K or 10°C). White contours and blue shading, tropopause wind speed (interval 10 m s^{-1} , color scale in the figure).

Figure 14 The winter North Atlantic stormtrack as derived from the ECMWF ERA40 reanalysis. Red contours and shading are trajectory density: the number of cyclones passing close to each of the grid points on average during each cold season. Contour interval three cases per season, thicker reference line nine cases. Blue bars indicate the average speed and direction along trajectories at each point. Only a subset of systems reaching a threshold amplitude and lasting a threshold time are included in this map. The large red arrow materializes the most frequent path taken by extratropical cyclones. The white contours and blue shading are the upper-level mean wind during that same period of 42 cold seasons, with the scale given in the figure. Figure constructed with the tracks obtained by Joly, B., Ayrault, F. from Météo-France, from the ECMWF ERA40 reanalysis 6-hourly fields.

figure. Actually, their distribution within the 6-month period considered can be computed and they turn out to be most frequent in January and February. The mean lifetime is 5 days but the median lifetime is 3 days: there is a large dispersion.

The combination of the large-scale jet stream, with its accompanying meridional gradients of temperature and tropopause height together with the main tracks of cyclones forms a large-scale dynamical system called a stormtrack.

Consider now the whole of the Northern Hemisphere. The data employed to construct **Figure 15** is the first generation European Centre for Medium-Range Weather Forecast (ECMWF) reanalysis, called ERA15 (ECMWF Reanalysis, 15 years, 1979–94), supplemented with operational analyses and the equivalent National Center for Atmospheric Research (NCAR) reanalysis. The cold season is also reduced to the more traditional months of December, January, and February (the so-called DJF season). The tracking technique is more general than the one just described in that it can be applied to a variety of features: vorticity maxima as above but pressure anomaly minima as well (which forces to define what an anomaly is) or vorticity minima (anticyclone tracking) or ascending velocity maxima. Nonetheless, the figure shown is for vorticity maxima tracks. Densities and mean speed compare reasonably well over the North Atlantic with the more recent one in **Figure 14**. This is worth mentioning, as it shows results are not too sensitive to the remaining arbitrariness of the approaches as well as to the dataset. Beside the North Atlantic, there are other areas where extratropical cyclones are to be observed. One is the North Pacific: the density map indicates that the trajectories followed by the systems in the case study above are typical of that region. The western Pacific off Japan appears to be an area where cyclones are even more frequent than in the Atlantic. There are also very frequent cyclones just east of the Rockies and over the continental United States, the Great Lakes especially. Other favored locations are Siberia at high enough latitude

and the Mediterranean. This spatial distribution suggests that extratropical cyclones, while not absent from some continental areas, are primarily a maritime atmospheric phenomenon.

Many properties can then be computed to provide sound statistical informations on cyclones, using the trajectories. One key concept introduced with the case study is that of life cycle. The density of appearance of a new cyclone can be mapped, as well as the density of disappearance. One such map is included in **Figure 15**, or genesis. This map confirms the existence of maxima of initiation of new systems off the eastern coasts of the United States and of Japan, that is on the westernmost part of the stormtracks. However, there are also more localized and more active areas of genesis over Alberta in Canada and Colorado in the United States, always just east of the Rockies and near Mongolia, northeast of the Tibetan Plateau. There is a weaker maximum of genesis east of that other large-scale mountainous area in China. The Gulf of Genoa in the Mediterranean also shows up here as a place of frequent genesis. Cyclones disappear in places traditionally known as the Icelandic Low or the Aleutian Low.

Several properties relating to the growth of the cyclones can also be derived. **Figure 15** includes a map of mean growth rate defined as $\bar{\sigma} = \zeta^{-1} \Delta \zeta / \Delta t$, where ζ is the vorticity amplitude along the track. The largest growth is observed over the Rockies and at the western beginnings of the main oceanic sets of tracks in the Atlantic and the Pacific. Their average values are about $0.4\text{--}0.6 \text{ day}^{-1}$ ($\sim 5\text{--}7 \times 10^{-6} \text{ s}^{-1}$). The number of growth phases along the tracks can also be monitored. For example, in the ERA40 sample in the North Atlantic, it is found that about 17% of the cases decay after they have first been detected, but only 4% never grow again at later stages. About 40% undergo a 'standard' life cycle, that is a single growth phase peaking some time between genesis and lysis. Complex life cycles happen to the others, in a form or another, with 28% having two growth phases. The mean lifetime when

Figure 15 Results from an automatic 'feature' tracking algorithm covering the Northern Hemisphere wintertime (DJF), based on a nonhomogeneous mixture of ECMWF ERA15 reanalysis, ECMWF operational analyses, National Center for Environmental Prediction (NCEP) reanalysis. The feature selected here is 850 hPa relative vorticity maxima. Upper left: track density over areas of 5° spherical caps per month. Upper right: mean speed and velocity. Lower left: genesis density, or density of first detection of new systems, same convention as for tracks. Lower right: mean growth rate, that is average value of $a^{-1}da/dt$, where a is the amplitude, in units of day^{-1} . From Hoskins, B.J., Hodges, K.I., 2002. A new perspective on northern hemisphere winter storm tracks. *Journal of Atmospheric Sciences* 59, 1041–1061.

maximum amplitude is reached is 1.3 days, the median 1.8 days. Comparing with the total lifetimes, this suggests, as seen with the Low M case above, that growth rather takes place at the beginning, the first 2 days in general and it is followed by a rather long decay phase of several days, with a large case-to-case variability.

It is also possible to document extratropical cyclones in the Southern Hemisphere using the same data and techniques. Some results obtained with the ERA40 reanalysis are shown in [Figure 16](#) and for south hemisphere winter: the months of June, July, and August. This figure offers a comparison of vorticity maxima tracking against pressure anomaly minima. Both indicate a simpler distribution in the Southern Hemisphere than in the northern one. There is a single semicircular maximum of track densities extending a bit more than 180° from the central southern Atlantic Ocean to the southern western Pacific, with relative maxima in the Indian Ocean to the southwest of Australia and south of New Zealand. Genesis preferably takes place just east of the Andes in Argentina and on the coast of Antarctica, south of New Zealand. Growth rates have the same magnitude as in the Northern Hemisphere.

Composite Types of North Atlantic Extratropical Cyclones

The use of reanalysis data enables to make a further step toward portraying the generic or 'typical' extratropical cyclone. In this section, the first generation ECMWF reanalysis, ERA15, is employed in order to build composites representative of hundreds of individual cases, described entirely numerically with a set of consistent fields and of known representativeness.

ERA15 covers the period 1979–93. It is an extraction of the extended winter season previously mentioned (15 October–15 April) over a domain centered over the North Atlantic.

The trajectories of 850 mbar vorticity maxima have been constructed as in the previous section. In order to distribute events into classes, the large state vectors that result from extracting fields in boxes of size of about 2500 km centered on the low-level vorticity maxima along the trajectories are reduced by a principal component analysis. The remaining components are distributed into classes using ascending hierarchical classification. Paradigms of situation conducive

Figure 16 Same as Figure 15 but covering the Southern Hemisphere wintertime (JJA) and based on the homogeneous ECMWF ERA40 reanalysis. Upper left: 850 hPa vorticity maxima track density over areas of 5° spherical caps per month. Contours are mean amplitude, contour interval $5 \times 10^{-6} \text{ s}^{-1}$, two reference contours are shown below the panel. Upper right: track density resulting from tracking mean sea-level pressure minima (shading) and mean amplitude (contours, contour interval 2 hPa, two contour references provided in the panel). Lower left: genesis density of the tracks of 850 hPa vorticity maxima. Lower right: mean growth rate of maximum vorticity amplitude in units of day^{-1} . From Hoskins, B.J., Hodges, K.I., 2005. A new perspective on southern hemisphere storm tracks. *Journal of Climate* 18 (20), 4108–4129.

to cyclogenesis are then obtained by averaging the original fields within each class.

Study of the distributions of amplitudes, of durations, and of the various growth phases discourages the automatic classification of full life cycles. Two particular stages have been isolated. One is the 12-h period centered on the 0 h time of each case, extrapolating a location for the field extraction at -6 h. This phase is called the initiation of a new cyclone. The other is the 24-h period preceding the time of maximum amplitude; this is called the maturation phase and it generally includes the period of maximum vorticity growth undergone by each case.

Summary of Genesis Situations

The classification of initiation has 12 classes. The best previous studies dealt with two dozens of cases, while this one uses nearly 6000 cases. As it is impossible to fully account for all the classes here, composites are gathered into ‘families’ of which there are five.

The most frequent family corresponds to the genesis of a cyclone on the northern side of the baroclinic zone, in the cold air (28% of cases). Nearly as frequent, there is a family that comes close to the extensively studied frontal instability problem (24%, Figure 17). It departs from the idealized situation on one critical aspect: the flow is three-dimensional (3D) and the new cyclone forms at the end of the gradient zone, below a jet entrance. This generic situation shares some aspects with the initiation of Low M in the case study above, except for the apparent absence of an equivalent of Low P. Neither of these families seems to feature an upper-level precursor of the cyclogenesis. The next two, on the other hand, do have such a preexisting structure of cyclone scale: the class that corresponds to a surface development induced by an upper-level disturbance and a new family where the precursor is a full-scale cyclone that splits into the old and a new system. The former seems to account for the initiation of Low P. As will be seen in the next section, it is also a well-known situation, indeed a kind of

Figure 17 One of the initiation Class W composite at times (from left to right) -6 h, 0 h (first detection time of an individual vorticity maximum), and $+6$ h, at 300 hPa (top) and at 850 hPa (bottom). The fields on the top row are wind vectors (blue barbs, kt) colored according to speed so as to highlight the jet-flow structure (the darkest blue above 40 m s^{-1}) and relative vorticity ζ_r (light purple lines, contour interval $2 \times 10^{-5} \text{ s}^{-1}$, negative contours dashed). The green-shaded background field is the 600 mbar relative humidity (contour interval 10% , white for values larger than 90% , color darker for smaller values). Bottom fields are relative vorticity (as on the top, with darker contours) and equivalent potential temperature θ_e (brick-red thin contours and shading, interval 3 K , limit between blue-green shade and light orange 300 K). The 850 mbar wind is also shown as above, the darkest blue threshold is changed to 10 m s^{-1} . The boxed arrow is a compass indicating the average direction of the geographical north, since the area shown is rotated. Adapted from Ayrault, F., Joly, A., 2000. Une nouvelle typologie des dépressions météorologiques: classification des phases de maturation. *Comptes Rendus de l'Académie des Sciences Paris, Sciences de la Terre et des planètes* 330, 173–178.

paradigm. A single picture summary of each family is shown in [Figure 18](#).

Summary of Development Situation

The maturation phase composites show seven classes. [Figure 19](#) shows some of the morphological characteristics of Class A, the one that undergoes the largest deepening ($-25 \text{ hPa}/24 \text{ h}$) and happens in 12% of the cases: it is what some authors have termed the meteorological ‘bomb.’ Centered on the low-level component of the system, the figure clearly depicts the phase change between this and the upper-level component: as there are independent studies of these strong cases, this class validates the approach. Note, in particular, the similarity between this evolution that combines together about a 100 cases and the growth phase of Low M in [Figure 12](#).

Class B, although not deepening, remains in warm air and yields significant precipitations. An interesting characteristic of this type is that it occurs in rather strong baroclinic zones, like Class A and with the same frequency. Yet, it does not develop strongly ([Figure 20](#)). The magnitude of the baroclinity does not explain the two different behaviors, and this questions explanations in terms of simple instabilities. Class B does not have the upstream upper-level signature that Class A shows well.

The other types correspond to cyclones deepening between 9 and 15 hPa in 24 h . These classes show, in common with Class A, the presence of a well-defined upper-level signature. One feature that discriminates these types is the shape of the upper-level jet and the position of the cyclone relative to it ([Figure 21](#)). Using time filtering to separate the cyclones and their environment, it is possible to estimate the energy transfers. The preferred energy conversions are similar for all the developing classes and correspond to the early twentieth century idea that cyclones develop by converting the energy contained in horizontal gradients of temperature into wind. This is called baroclinic interaction. In that sense, the core physical mechanism for growth is the same for all these types.

The method employed yields so far two sets of composites. A fundamental result comes from the clear separation between these two sets: the subsequent amplification of a cyclone does not necessarily involve the same processes as its genesis. Indeed, while baroclinic interaction is the only significant process leading to large amplitudes, it is the dominant mechanism in 20% of the initiations at best.

Altogether, case studies such as the well-documented FASTEX cases and many others and the climatological composites enabled by the reanalyses indicate (1) that there are distinctive structural features between rapid deepeners or ‘bombs’ on the

Figure 18 A single-time summary of three of the other families of initiation composites. The structures are shown at the time of the first detection of an individual vorticity maximum, that is the appearance of a new cyclone. From left to right: a class of cold air cyclogenesis; cyclogenesis induced by a preexisting upper-level precursor; and a class of cyclogenesis resulting from the apparent aft-splitting of an older cyclone. The fields are displayed as in [Figure 17](#). Adapted from Ayraut, F., Joly, A., 2000. Une nouvelle typologie des dépressions météorologiques: classification des phases de maturation. *Comptes Rendus de l'Académie des Sciences Paris, Sciences de la Terre et des planètes* 330, 173–178.

Figure 19 Example of one of the types of composite mature extratropical cyclone, the most intense ones (Class A). The composite structure is shown at times -24 h, -12 h and at the time of maximum amplitude (from left to right), at 300 mbar (top) and at 850 mbar (bottom). The fields are mean sea-level pressure (black contours, interval 5 hPa, thicker reference 1015 hPa), 850 hPa moist potential temperature (red contours, interval 3 K), 850 hPa relative vorticity (purple contours and orange shading, interval $2 \times 10^{-5} \text{ s}^{-1}$, negative contours dashed), as well as in the top panels the 300 hPa wind (barbs) and wind speed (white contours, blue shading, interval 10 m s^{-1}) and, similarly represented, the 850 hPa wind and wind speed in the bottom panels. Derived from Ayraut, F., Joly, A., 2000. Une nouvelle typologie des dépressions météorologiques: classification des phases de maturation. *Comptes Rendus de l'Académie des Sciences Paris, Sciences de la Terre et des planètes* 330, 167–172.

Figure 20 The mean 24-h pressure deepening $\Delta p/24 \text{ h}$ of the seven classes of maturation phases are plotted against the low-pass average baroclinity, the temperature gradient of their environment. From Ayrault, F., Joly, A., 2000. Une nouvelle typologie des dépressions météorologiques: classification des phases de maturation. *Comptes Rendus de l'Académie des Sciences Paris, Sciences de la Terre et des planètes* 330, 167–172.

entrance side of a stormtrack and on the exit side and (2) that the maturation of a cyclone definitely involves finite-amplitude interactions between low level and upper level. The basic mechanism, that can be called baroclinic interaction, is understood in broad terms (see below), but many of its critical properties (existence of amplitude thresholds, critical distances, and the likes) are not yet known.

Other Types of Cyclones

So far, extratropical cyclones that are closely associated with a baroclinic area or jet flow have been discussed. The baroclinic area provides their energy and leads to a single broad mechanism for development, with several variants. They are the most common ones. However, there exist other kinds of extratropical

cyclones that depend on profoundly different mechanisms. Three examples deserve to be mentioned.

One kind is termed polar lows. As their name suggest, they are cyclones that are observed at high latitudes, in cold air. They appear to start as quite small-scale systems (compared to the more standard 'baroclinic' systems) but they are able to develop very strong low-level winds. The mechanism that makes polar lows cousin to tropical cyclones is they are dependent on air–sea interactions. While tropical cyclones subsist on latent heat fluxes (or the evaporation of water from the sea), polar lows depend on the temperature difference between very cold air and a relatively warm sea. Some polar lows grow in scale and may turn into more classical weather systems interacting with some upper-level flow. It must be noted that systems of that kind, more symmetrical than standard extratropical cyclones, sometimes with an eye, have been observed in the Mediterranean Sea, although they cannot be termed either tropical or polar.

Another kind, also well represented in the Mediterranean area, is lee cyclones. These cyclones form in the lee of a large-scale orographic barrier, such as the Alps. The cyclogenesis is triggered by the interaction of a preexisting weather feature (such as a front or a trough) with the orography. The global view given by the reanalysis shows that most large mountainous barriers induce a cyclone initiation area in their lee.

A final kind of low is that associated with a high-pressure center located to its poleward side. The low and high are coupled: they form what is called a block. Blocks are persisting large-scale structures; their lifetime is longer than that of baroclinic cyclones and they are larger than the baroclinic cyclones. Their vertical structure is also simpler. Blocks form at the end of stormtracks and persist by deriving their energy from the baroclinic activity within the stormtrack upstream of them. The lows that are part of a block shows bursts of activity, with transient precipitating features that tend to rotate around the

Figure 21 A single-time summary of the other classes of mature stage composites. Structures are shown at the time of maximum amplitude. From left to right: the weak wave class (Class B); the class of cyclone maturing between two upper-level jet streaks (Class C); the class of cyclones developing when reaching a diffluent zone while coming from the warm side (Class D); an example of a class of cyclones linked to a marked upper-level trough (Class E); and the most populated class of nondeveloping systems (Class G). The fields are displayed as in Figure 17 except for the wind shown above 50 kt. Adapted from Ayrault, F., Joly, A., 2000. Une nouvelle typologie des dépressions météorologiques: classification des phases de maturation. *Comptes Rendus de l'Académie des Sciences Paris, Sciences de la Terre et des planètes* 330, 167–172.

low center (quite unlike the fronts of a baroclinic system which remain fixed relative to the center).

Previous Recent Conceptualizations of Extratropical Cyclones

The evolution of the understanding of extratropical cyclones is tied to the progress of two areas: better observations on the one hand, and on the other the introduction into meteorology of new mathematical tools for physics, allowing assumptions and their consequences to be quantified and checked. From that point of view, early attempts using concepts like the thermal cyclone or the polar front cyclone, although seminal in some respects, have not been very successful.

Upper-Level Induced Development Model

The emergence of operational meteorology accompanying the development of aviation led to better coordinated observational networks. The surface measurements benefited from the first ships able to hold a fixed location in the ocean. Most importantly, upper-air observations over continents became more frequent; they used sondes attached to balloons. Radiosondes transmitting their data while ascending were introduced, removing the need to recover the recorded measurements after the balloon burst and the sonde fell in some unlikely place. In 1935, a 'coordinated ascents' experiment on the scale of western and northern Europe took place. For the first time, a few mature cyclones were sampled in three dimensions.

The upper-level structure of the flow about extratropical cyclones was then quite clearly obtained. The wind increased with height much more rapidly near the cyclone center than away from it. A very clear vertical tilt with height of the minimum pressure location was definitely shown to exist. It took some time to make something of the wind distribution: ultimately, and with much further observations, it was recognized to be organized in meridionally localized streams of air, called jet streams. But the importance of the vertical tilt and the related upper-level mass distribution was grasped very quickly, partly because it had been anticipated both with observations and theoretically on several occasions before. Several approaches have since been developed. One is called 'development.' This had been outlined shortly before the 1940s by the British scientist Sutcliffe, who proposed that the emergence and amplification of a surface cyclone resulted from the influence of a preexisting upper-level trough in a broad baroclinic zone (rather than an extreme front). This view is supported by simplifying fundamental equations, rather than linearizing them, and concentrating, in particular, on vorticity dynamics. In problems where rotation is important, looking at vorticity is a good tactic.

Along this line of thought, the German meteorologist Kleinschmidt put some flesh on the concept of the upper-level component of an extratropical cyclone and its relation to vorticity. Using the homogeneous and extended network of radiosoundings available over Europe in 1943, he built a striking 3D picture of this structure. Furthermore, he gave the description in terms of a quantity akin to vorticity and called

potential vorticity. He particularly undertook to show that, under certain assumptions, it is possible to derive the wind and temperature distributions from that of potential vorticity, a process called inversion.

Sutcliffe and Kleinschmidt are, together with the Swede Petterssen and a few others, representatives of a school of thought that made the most of available observations to conclude that cyclones are largely caused by finite-amplitude interactions of some preexisting 'structures': vertically confined vortices, baroclinic zones or jet streams, fronts, and the like. However, until recently, they represented a minority among those attempting to understand cyclones.

Upper-Level Jet, Baroclinic Zone, and Baroclinic Instability

The school of Sutcliffe, Kleinschmidt, Petterssen, and others was in a minority because an elegant mathematical framework was set up in parallel and attracted most of the attention. Discarding the unrealistic extreme front model, Charney in California and Eady in England applied, in the early 1940s, the linear stability technique to the study of the properties of a simple broad baroclinic zone. This is an area of continuous and moderate transition from warm to cold air, which, as a consequence of rotation, is accompanied by a zonal wind increasing with height – an idealized form of the upper-level jet stream. This basic or initial flow indeed fits the observed average flow at midlatitudes much more reasonably than the extreme front model. This problem can be idealized to a point that allows analytical solutions to be derived that still share some properties with real cyclones. Most notably, the vertical tilt with height is part of the most unstable solution, together with reasonable spatial scales. This is the baroclinic instability theory of cyclogenesis.

These similarities made linear studies the preferred path to explaining natural phenomenon like the growth of cyclones. Most textbooks on dynamical meteorology depend heavily on linearized equations and stability problems. Very elegant general existence theorems have been derived.

Because it is so elegant and appealing to mathematically oriented minds, the instability model dominated the theoretical scene throughout the 1950s and 1960s. But because part of its elegance comes from mathematical tractability, only extremely idealized problems can be studied and the relationship with observations is the weak spot of all of this work. As a consequence (or measure) of this, the results have had little impact on practical forecasting aside from some guidelines for interpreting numerical model output.

Quasi-Geostrophic Model and Theoretical Results

In the early version of the instability approach, subtle simplifications were introduced at key points in the derivation, limiting the number of solutions. This practice is in fact very powerful as far as gaining an understanding is concerned. It was soon reconsidered more formally by Charney in terms of a scale analysis of the basic equations; this is called filtering on the basis of a balance assumption. A simplified set of equations specifically oriented toward understanding extratropical cyclones and their large-scale environment can be derived at the outset. This is the quasi-geostrophic model.

These equations represent cyclones and some of their behavior, but they exclude, for example, gravity waves. They include well-defined cause-and-effect relationships. In this framework, for example, vertical motion is the computable effect of the interaction between the thermal and horizontal wind fields.

It is important to realize that this model is the common ground of both the intrinsic instability approach and the finite-amplitude interactions approach. With hindsight, it is easy to show that Sutcliffe's calculations are based on an early form of the quasi-geostrophic filtering and so are Eady's. Potential vorticity inversion, as outlined by Kleinschmidt, is a well-posed classical Poisson problem in this framework. The current theoretical understanding of cyclones undoubtedly rests on the quasi-geostrophic framework.

The case study and most of all, the study of reanalyses introduces the relevance of the baroclinic zone with a jet-stream flow as the environment of extratropical cyclones. It has also shown the diversity of types and life cycles only part of which are understood.

The Mechanisms of Cyclone Development

This section aims at providing a simple dynamical understanding of the main mechanism behind the development of most extratropical cyclones called baroclinic interaction and continues to discuss various ways it can take in the atmosphere.

Thermal Wind Balance

The various observational studies mentioned above allow retrieval of a number of properties of extratropical cyclones. Thus, on the scale of such systems, the vertical profile of temperature barely departs from that given by assuming that the atmosphere is in hydrostatic equilibrium. The horizontal wind is also quite close to the wind deduced from the distribution of mass assuming geostrophic equilibrium. The hydrostatic equilibrium relates the vertical distribution of mass to temperature; the geostrophic equilibrium relates the horizontal distribution of mass to the wind. Combining the two means that a cyclone evolves in a state that preserves some kind of equilibrium between wind and temperature, called thermal wind balance (Figure 22). The evolution of an atmosphere remaining close to thermal wind balance is described by the quasi-geostrophic system of equations. With a proper choice of vertical coordinate z (pressure rescaled as a height), this can be expressed as:

$$f \frac{\partial u}{\partial z} \sim -\frac{g}{\theta_0} \frac{\partial \theta}{\partial y}, \quad f \frac{\partial v}{\partial z} \sim \frac{g}{\theta_0} \frac{\partial \theta}{\partial x}, \quad [1]$$

where x is oriented eastward, y is oriented northward; g/θ_0 is related to the scale height of the atmosphere $H_s = R_a \theta_0 / g$, with R_a the perfect gas constant for air; u is the zonal wind, v the meridional wind; and θ is the potential temperature, a temperature conserved in adiabatic displacements. The wind and temperature fields are therefore not independent: they can be described in terms of just one field, either the geopotential ϕ or the quasi-geostrophic quasi-potential vorticity q_g . The latter is conserved by geostrophic displacements, whereas the

Figure 22 Schematic showing an idealized baroclinic zone, the environment within which extratropical cyclones develop. It is an area of reinforced but continuous horizontal thermal gradient in thermal wind balance with an upper-level jet flow. In the simplest case, the baroclinic zone is assumed to be homogeneous in the zonal (x) direction, so the scheme is isolating a segment. Adapted from Malardel, S., Joly, A., 2000. EAO Anasyg/Presyg. Météo-France, Toulouse.

former is not. Both are related to one another by a Poisson-like equation:

$$q_g = \nabla_{qg}^2(\phi), \quad [2]$$

where ∇_{qg}^2 is a scaled Laplace operator.

The wind field, in particular, must be separated into two components: a geostrophic one ($u_g, v_g, 0$) such that:

$$u_g = -\frac{1}{f} \frac{\partial \phi}{\partial y}, \quad v_g = \frac{1}{f} \frac{\partial \phi}{\partial x}, \quad \text{with also } \theta = \frac{\theta_0}{g} \frac{\partial \phi}{\partial z}. \quad [3]$$

The other is a departure from geostrophy (u_{ag}, v_{ag}, w). This includes in particular the vertical motion w , which is directly responsible for the formation of clouds and rain.

Thus, the wind is not an independent variable, and in particular, the nongeostrophic component is a nontrivial function of the geostrophic wind and temperature. The physical idea is that the nongeostrophic component, which is zero when the thermal wind equilibrium is strict, appears as a response to geostrophic tendencies that, alone, would lead the system away from equilibrium. The sense of this response is to restore a state close to equilibrium. The nongeostrophic motion is caused by interactions between the geostrophic wind and the temperature that tend to break the thermal wind balance and is such that it has effects that oppose the cause that originally led to it (this is called negative feedback).

This can be written formally in terms of an equation for the vertical motion. It takes the form:

$$\nabla_{wqg}^2(w) = \mathcal{F}(V_g, \theta), \quad [4]$$

where ∇_{wqg}^2 is yet another scaled Laplace operator and $\mathcal{F}(V_g, \theta)$ describes how the geostrophic component of the flow forces vertical motion. The latter term is nonzero whenever the geostrophic wind tends to displace isotherms horizontally, or when isolines of the geostrophic stream function (close to ϕ) cross isotherms. Assuming zero vertical motion at the surface and the tropopause yields:

$$\frac{1}{\mathcal{V}} \int_{\mathcal{V}} w \mathcal{F} d\mathcal{V} < 0, \quad [5]$$

that provides a broad idea of the sense of the vertical motion, negatively correlated with the forcing $\mathcal{F}$ within an arbitrary volume.

Baroclinic Interaction

The vertical motion w is not only important because it is the direct cause of the formation of clouds in ascent zones. It is a key dynamical parameter. In particular, it controls the evolution of vorticity. The simplest form of the quasi-geostrophic equation of evolution of geostrophic relative vorticity $\zeta_g = \partial v_g / \partial x - \partial u_g / \partial y$ reads:

$$\mathcal{D}_g \zeta_g = f \frac{\partial w}{\partial z}, \quad [6]$$

where $\mathcal{D}_g = \partial / \partial t + u_g \partial / \partial x + v_g \partial / \partial y$ is the geostrophic material derivative or the change of ζ_g following the geostrophic motion. This equation shows that the only remaining source of vorticity changes is the term called stretching. When the vertical velocity w increases with height, vortex tubes are stretched and this increases their vorticity.

At any given time, the extratropical troposphere shows a planetary-scale wavy pattern with a broad area of increased meridional gradients (the main baroclinic zone), together with a number of vortex-like features of various scales. Some of these vortex structures are like filaments coming out of the planetary polar vortex, others are cut off from this and look like isolated or sometimes coupled maxima or minima drifting in the vorticity field.

Consider therefore the following idealized situation: a single vorticity maxima (say) trapped near the tropopause close to a homogeneous baroclinic zone (Figure 23). Because of thermal wind balance, the latter can be seen either as a deep area of reinforced meridional temperature contrast or as where the upper-level jet stream is. The vorticity maximum and the baroclinic zone interact with each other in the sense that the stream function signature of the vorticity maximum crosses the isotherms of the baroclinic zone (and vice versa). This interaction leads to some response in the nongeostrophic wind field; in particular, it causes vertical motion. The vertical motion is strongest where the geostrophic cross-isotherm flow is the strongest (to first order), namely in two locations: just downstream (eastward) and just upstream (westward) of the vorticity maximum in the flow oriented by the jet stream. The rule of thumb is that the vertical motion opposes the effects of the geostrophic wind on the isotherms. On the downstream side of the vorticity maximum in the troposphere, the cyclonic flow leads to warming and cooling on the upstream side. This is opposed by tropospheric ascent downstream and descent upstream.

Figure 23 Vertical cross section in the same framework as in Figure 22 showing some aspects of an upper-level vorticity anomaly in the jet flow. Such a structure propagates but does not develop or, at least, not fast. However, it is a simple model of upper-level precursor. Adapted from Malardel, S., Joly, A., 2000. EAO Anasyg/Presyg. Météo-France, Toulouse.

Consider now the effect of this vertical velocity field on the vorticity maximum. There is stretching on the westward side, nothing at the level of the maximum and squeezing on the eastward side. This means that the vorticity maximum will propagate upstream (toward the west), in other words it will move more slowly than the wind in the jet, but will not amplify since no vorticity is created at its core. Here, we have a simple model of a structure that can persist for some time, move relative to main flow but will remain barely visible in terms of 'weather.' This is one simple example of a precursor structure. Away from the surface, as assumed here, it is little affected by friction. However, this kind of vorticity monopole is generally dispersive, which sets a limit to its 'useful' lifetime.

Consider now the effect of that vertical velocity field on the other boundary, in this case, near the surface. The ascent is a source of stretching for surface-based vortex tubes. So near-surface vorticity is generated below the ascent, slightly downstream of the upper-level precursor. This is the source of cyclone development contemplated by Sutcliffe and Petterssen.

Similarly, an isolated surface-based vortex is accompanied by the same kind of vertical velocity field as an upper-level one when interacting with a baroclinic zone (Figure 24). This vortex will propagate downstream (toward the east) but, similarly, it will not develop. Not only these low-level precursors are also dispersive, but also they are affected by friction. Nonetheless, they may exist for short periods. They also have an effect on the vorticity dynamics on the other boundary, the tropopause.

Rapid mutual development of such vortices in a baroclinic zone takes place when they are located relative to one another in a way such that their associated vertical velocity zones stretch the vorticity maximum at the other boundary. In this case, both vortices amplify each other: this is the essence of baroclinic interaction. This happens as long as the low-level vortex is located downstream of the upper-level one (Figure 25). If the

Figure 24 Same as Figure 23, but for a low-level vorticity anomaly. Its behavior is the same as the upper-level anomaly. Adapted from Malardel, S., Joly, A., 2000. EAO Anasyg/Presyg. Météo-France, Toulouse.

Figure 25 Constructive baroclinic interaction takes place when two structures like those shown in Figures 23 and 24 influence each other as shown in this cross-section, amplifying each other. Adapted from Malardel, S., Joly, A., 2000. EAO Anasyg/Presyg. Météo-France, Toulouse.

low-level vortex is found upstream of the upper-level one, then the interaction is destructive and the composite system collapses rather than amplifies.

This shows how the ideas of balance lead to a characteristic constraint on the vertical structure of a developing cyclone. The baroclinic zone provides the thermal energy available for conversion into cyclone wind. The low-level vorticity signature of the cyclone must be located downstream of the upper-level part, as shown in the climatological composites, in order for a balanced circulation to amplify as this energy is converted.

From this elementary description of the mechanism of baroclinic interaction, one can spot a number of critical parameters. The process depends on the influence of a vorticity structure on the other horizontal boundary; the stronger this influence, the more efficient the process. This is clearly related to the vertical scale H_ζ of the initial structures and to the way the medium (the baroclinic zone) opposes or aids this influence. Concerning the first point, taking into account the fact that potential vorticity is quasi uniform in the troposphere makes the vertical scale a simple function of the horizontal one L_ζ with $H_\zeta \sim L_\zeta \times f/N$. Here, N is the vertical static stability of the troposphere. This vertical scale must be of the same order as the depth of the troposphere H . In short, only anomalies with a horizontal scale larger than some threshold may amplify efficiently through baroclinic interaction. This threshold is of the order of the Rossby radius of deformation $L_R = HN/f$. Below this scale, they can only propagate (or disperse). The critical property of the medium is its potential vorticity, which, at the level of quasi-geostrophic theory, is mostly related to the static stability. The smaller the potential vorticity is, the easier the interaction is. This is included in the definition of the Rossby radius.

The other parameters include the vertical phase between the vorticity components. For systems that are locked in phase, there is an optimum phase tilt that allows for the fastest sustained growth over a long time. However, the composites do not show vertical phase locking and the problem must be seen differently. The climatological study reveals that the observed timescale of development is about 24 h: it can then be shown that systems that are not phase locked (with a tilt that changes with time) amplify significantly more rapidly over a wider range of scales during this timescale. A further parameter is the initial distance between the structures, when two potential precursors exist at both boundaries. Below some value, a single powerful cyclone will result from the interaction. Above some value, each precursor will tend to generate its cyclone, but as this process is building up slowly, one will notice two small amplitude systems. The duration of the interactions is another parameter. Finally, the nature of the underlying surface is also important in determining when an amplifying interaction may start: it has to create more kinetic energy than is dissipated by friction. Although the finite-amplitude maturation of an extratropical cyclone may take place over land (unlike a tropical cyclone), its early growth is easier over sea because of the reduced friction.

The Two Sources of Cyclone Growth in a Balanced Flow

The preceding paragraphs discuss how the shape of the composite system temporarily or permanently made up of two vorticity maxima at low level and upper level enables it to grow

from tapping energy from the existence of a horizontal temperature gradient in its environment. The critical aspect of the shape is that it must be elongated against the thermal wind that accompanies, in a rotating frame, the horizontal temperature gradient.

It is useful for future reference to provide some formalism to this type of growth through balanced interactions. The approach is to write how the energy of the perturbation cyclone can grow. At the level of the 'dry' adiabatic quasi-geostrophic theory, there are only two sources that can feed the growth of a perturbation in a quasi nondivergent environmental flow. One is the baroclinic interaction just explained. In a more general situation, the baroclinic interaction as an energy source term can be written as $S_{bc} = \mathbf{F}' \cdot \mathbf{\bar{B}}$ with:

$$\mathbf{F}' = \left(\frac{g}{\theta_0} \right) \left(\frac{v'_g \theta'}{N}, -\frac{u'_g \theta'}{N} \right), \quad [7]$$

$$\mathbf{\bar{B}} = \left(\frac{g}{\theta_0} \right) \left(-\frac{\partial \bar{\theta}}{\partial y}, \frac{\partial \bar{\theta}}{\partial x} \right) = \left(\frac{f \partial \bar{u}_g / \partial z}{N}, \frac{f \partial \bar{v}_g / \partial z}{N} \right). \quad [8]$$

In these equations, the properties of the environment are indicated with an overbar $\bar{\cdot}$, those of the cyclone or any other structure embedded in it are indicated with $\cdot'$. This implies that a given situation has been split into at least two parts, but it does not imply anything about amplitudes. The $\mathbf{\bar{B}}$ vector represents the baroclinity of the environment as a vector aligned with the thermal wind, that is oriented along the jet-stream flow. The vector $\mathbf{F}'$ represents on first inspection the heat fluxes associated to the perturbation. However, in a balanced flow, both u'_g and θ' depend on the perturbation geopotential ϕ' . Using this property, these fluxes turn out to be related to the shape of the perturbation in each vertical plane. It is another way to recover the need for the westward vertical tilt to grow in a balanced zonal jet.

The other source of growth is called the barotropic interaction: in this case, the perturbation extracts its own kinetic energy from the kinetic energy of the environment. The barotropic interaction as an energy source reads $S_{bt} = \mathbf{E}' \cdot \mathbf{\bar{D}}_f$, where:

$$\mathbf{E}' = \left(\frac{1}{2} (v_g'^2 - u_g'^2), -u'_g v'_g \right), \quad [9]$$

$$\mathbf{\bar{D}}_f = \left(\frac{\partial \bar{u}_g}{\partial x} - \frac{\partial \bar{v}_g}{\partial y}, \frac{\partial \bar{v}_g}{\partial x} + \frac{\partial \bar{u}_g}{\partial y} \right). \quad [10]$$

The vector $\mathbf{\bar{D}}_f$ is the deformation field of the environment. The $\mathbf{E}'$ vector can be related to the horizontal anisotropy of the cyclone perturbation, that is to its shape in the horizontal plane. At the level of the quasi-geostrophic assumption, again the terms of $\mathbf{E}'$ depend only on the geopotential acting as a stream function. In this case, $\mathbf{E}'$ is related to the horizontal tilts of the cyclone perturbation. It can be shown that growth takes place in a simple situation when the perturbation tilts against the shear (Figure 26). In more general situations, several angles come into play, describing the shape of the perturbation or principal axes of deformation.

Of course, these same terms can also account for energy transfers from the perturbation to its environment. This is why they will be encountered again.

Figure 26 Schematic illustrating how the shape of a perturbation (purple contours and black dash-dotted axes) leads it to grow or to vanish in a situation where shear is present both horizontally and vertically. Perturbation structures are shown at two times denoted 1 and 2. The vertical shear implies the presence of a horizontal gradient of temperature. Left side: the perturbation grows from both the baroclinic (vertical tilt) and barotropic (horizontal tilt) interactions. Right side: the perturbation vanishes because it loses energy by both mechanisms.

Conditions Favoring Cyclone Development

Various aspects have been studied, either using linear models or by performing sensitivity experiments in nonlinear runs. A first kind of experiment is to change the physics of the model, such as by removing cloud processes. More recently, the initial conditions are also used to test ideas.

To summarize, it is found that low static stability, weak environment deformation, small horizontal shear in the jet stream, and latent heat release contribute to accelerating and strengthening the development of extratropical cyclones. The role of turbulent fluxes is more complex. The importance of low friction at the beginning of life cycles has already been stressed. Heat fluxes have contradictory effects within a growing cyclone. However, large heat fluxes ahead of or prior to the coming of a cyclone may reduce static stability by mixing and create a medium that will favor rapid growth; in other words, they reduce the Rossby radius L_R . This is called preconditioning.

Brief Review of Linear Stability Problems Relating to Cyclogenesis

Originally, the basic mechanism was called baroclinic instability. It was first derived by solving the linear stability problem that results from linearizing balanced equations with respect to a simple baroclinic flow. One solution is emphasized and somehow associated with a developing cyclone, the most unstable normal mode. The necessary vertical tilt is nicely predicted by this approach. However, the timescale is not properly handled. Introducing such unstable solutions into nonlinear models, while it allows the description of some of the structure changes, rather emphasize this too slow timescale problem. This raises enough doubts to lead to cast the problem differently, leading to look for more general solutions to obtain considerably larger amplification rates together with rapidly changing structures in the linear framework. In both these approaches, the view still persists that cyclones result from amplifying a barely measurable initial perturbation in a smooth large-scale baroclinic flow.

Other aspects that have been analyzed in terms of linear instabilities, either standard or generalized are slightly more complex basic flows such as two-dimensional fronts,

characterized by a large low-level relative vorticity maximum. Strong normal modes can be found when the vorticity maximum corresponds to a large amplitude, narrow potential vorticity anomaly, such as can be generated by latent heat release in a real frontogenetic process. More recently, the possibility of instabilities in time-dependent flows has been examined. The aim is to determine in particular the role of the background deformation field that may act on the basic flow, making a front stronger or creating areas of diffluence or confluence in a jet flow. The influence of the horizontal shear on the stability properties of a jet flow has also been examined in this way: a large horizontal shear makes the flow less unstable.

Potential Vorticity Attribution and Its Use in Theory Verification and Mechanism Finding

The framework outlined at the beginning of this section can be employed in other ways than finding the kinds of wavelike, possibly unstable solutions that it can support. This has brought out new possibilities for understanding less idealized flow configurations. Furthermore, these new approaches initially born from properties of the quasi-geostrophic representation of the synoptic scale atmosphere can be extended and practically implemented with far less constraining balance conditions. This has further enabled to start experimenting with realistic situations.

A first key idea is inversion of potential vorticity distribution. It is embodied in eqn [2], where the quasi-potential quasi-geostrophic vorticity q_g can be related to the geopotential ϕ following $\nabla_{qg}^2(\phi) = q_g(x, y, z)$. The situation can then be compactly summarized by the single distribution of potential vorticity $q_g(x, y, z)$ complete with boundary conditions. The vertical boundary conditions are important, they can take the form of the distribution of either the geopotential $\phi(z=0)$ at the surface and possibly at some upper boundary or the potential temperature $\theta(z=0) \propto \partial\phi/\partial z$ at the surface and at an upper boundary. From this small amount of information, the inversion of the operator ∇_{qg} yields the complete distribution of geopotential $\phi(x, y, z)$. From that, first the geostrophic components of the flow (u_g, v_g, θ) and then the ageostrophic ones, such as the vertical velocity w , can be recovered (using eqns [3] and [4]).

The next key idea is to see the distribution of potential vorticity (including the boundary conditions) as the sum of several individual parts, each attached to some kind of 'object' in the flow. Typically, there will be a large-scale part representing a baroclinic zone and a number of anomalies. Each of these parts should be represented by a piece of potential vorticity distribution δq_{gn} together with the corresponding boundary conditions, $\delta\theta_n(z=0)$, say. The situation is therefore now seen as the sum of these parts: $q_g(x, y, z) = \sum_N \delta q_{gn}$, similarly with the boundary conditions. The flow corresponding to one of these parts can be inverted from its own potential vorticity distribution δq_{gn} and its associated boundary conditions: this will provide anomalies of the geostrophic components ($\delta u_{gn}, \delta v_{gn}, \delta\theta_n$) and other fields. To the extent that the addition theorem applies, the total flow previously represented as a whole has then been decomposed into distinct anomalies, each related to a particular feature of the potential vorticity distribution including boundaries. The wind or the temperature at some place can now be seen as the sum of the anomalies

each attached to some aspect of the potential vorticity distribution: this is called attribution. In principle, the total flow is exactly the same as the one resulting from inverting the total potential vorticity distribution q_g . But having decomposed it into several consistent anomalies opens a completely new avenue: now, the dynamical interactions between the different parts of the flow can be computed and should provide a direct proof of, say, the explanation of the appearance of some new system. Conversely, a given potential vorticity structure and its boundary conditions can be removed from some situation, together with that part of the flow that has been attributed to it. Then, it is possible to see exactly what happens in the absence of this removed structure.

One application of these ideas is to linear instability theory verification in a real case. Linear theory has it that extratropical cyclones can be identified, at least initially to a linear perturbation that can be computed knowing the large-scale flow alone. The theory provides the structure the new cyclone should have as well as key properties such as a phase speed and a rate of growth: verifying the theory means comparing such predictions with the observed cyclone. In the real atmosphere, the flow is one, while in the theory, the flow is by construction split into the environment and the linear perturbation. To verify the theory, the real flow must be split as well, this is known as the separation problem. Potential vorticity attribution and inversion enables to solve that problem by working on a single field, potential vorticity, from which the other dynamically consistent anomalies of wind, temperature, and others can be deduced. This provides a representation of a real cyclone in perturbation form quite comparable to a predicted vector, it also gives a chance to model the large-scale flow without the event of interest that is required to compute the relevant linear perturbation.

Figure 27 is a result of actually using these ideas extended to a very realistic primitive equation model to the 26 December 1999 intense storm that hit western Europe. Two diabatic primitive equation solutions have been obtained by extracting a small structure at initial time, one that has the event and the other that has most of the characteristics of the exceptional baroclinic environment of that case, except the storm itself. It is then possible to employ the theoretical framework without further approximation and to compare the predicted unstable modes with the storm represented itself as a perturbation. Two aspects of the theory are especially studied. One is a comparison of the properties of the real and predicted systems, focusing on their structures. One aspect of this comparison is illustrated in the figure. The other deals with the idea that precursor structures, although very different from the theoretical modes, trigger the cyclogenesis by exciting these modes. It appears that the classical predictions (scales, etc.) of such a theory are, for most of them, far away from the observed properties. It is clear that the structure of a generalized unstable vector has little to share with that of a real cyclone. Yet, a weaker, slower storm does occur as a result of applying the theory to the stormless trajectory.

Aside from this attempt, the verification of the theory of baroclinic instability has always been performed with poor standards compared with, for example, the quantitative verification of models of the boundary layer fluxes and profiles and some other processes. This is to a large extent due to the difficulty of splitting the observed flow without introducing imbalances that will spoil any conclusion nor without introducing too much subjectiveness. The theory is successful only in very, very broad terms.

Linear results may not be readily associated to real cyclones. However, they are a useful model for describing how forecast

Figure 27 The use of potential vorticity inversion enables a comparison between a real case of extratropical cyclone extracted from an analysis, denoted T1, and the perturbation obtained from an instability calculation of the flow without T1, denoted SV1. The figure shows one aspect of the structure focusing on the horizontal plane. It shows the 850 hPa potential temperature perturbation θ' for SV1 at (a) 0000 UTC 24 December 1999 (contour interval is 0.01 K) and (b) 0000 UTC 25 December 1999 (contour interval is 0.02 K). 850 hPa potential temperature perturbation θ' for T1 at (c) 0000 UTC 24 December 1999 and (d) 0000 UTC 25 December 1999 – note enlarged contour interval of 1 K. Also shown is the wind speed on the 1.5 pvu surface of the trajectory (shading interval is 20 m s⁻¹ above 40 m s⁻¹). From Descamps, L., Ricard, D., Joly, A., Arbogast, Ph., 2007. Is a real cyclogenesis case explained by generalized linear baroclinic instability? *Journal of Atmospheric Sciences* 64, 4287–4308.

errors amplify during the short ranges (the first day or so) in a numerical representation of the atmosphere.

As shown by the diversity of composite cyclones, the initiation from an upper-air disturbance envisioned by Sutcliffe and Petterssen is far from being the only mechanism. Other has to be explicated. Another use of potential vorticity attribution and inversion is to prove the importance of some supposed interaction in a realistic circumstance. Recall the case study in the initial section: it has been assumed that the genesis of Low M involves some interaction between Low P and the large-scale jet flow confluence zone. In fact, this assumption is based on experiments performed on a rather similar case especially well observed during the FASTEX project, a situation which is also close to the initiation Class W of composite cyclone formation. The 'cause' preexisting low can be isolated and part of the flow attributed to it. The wind attributed to a preexisting low-level decaying system approaching the western North Atlantic confluence zone from

the northwest is explicitly shown in two panels of Figure 28. Note that an upper-level anomaly is similarly isolated and the corresponding flow also explicated: again, this is quite like the case study above. So there are three components, the flow attributed to the decaying low-level cyclone that attributed to the upper-level anomaly and the rest. The sum of these components is the analyzed flow, it mostly features the jet inflow. The baroclinic interaction of the upper-level structure weakly sustains the decaying low but otherwise, at the time the new system forms, it acts away from where it appears. The barotropic interaction previously introduced between the decaying low and the lower part of the jet inflow, on the other hand, does happen exactly where the new low appears. Simply removing that decaying low-level system suppresses the appearance of the new system. In the case study above, the total flow bears the signature of Low P, quite strong and not yet decaying. This intensity allows a barotropic interaction with the low-level large-scale jet inflow (represented by the

Figure 28 Demonstration of an extratropical cyclone initiation mechanism using initial conditions modifications with potential vorticity inversion. Each column of three panels is the time sequence of an experiment with Météo-France global model with modified initial states. The left column features a preexisting low-level cyclone, showing the wind field that can be attributed to it (blue barbs). This wind field interacts with the reinforced baroclinic zone accompanying the jet-stream confluence aloft, and this creates a new system. The interaction is materialized by the single red contour with transparent red shading, a maximum of positive barotropic energy conversion. The right column shows the same sequence in the absence of that preexisting decaying cyclone: no new low forms, in spite of the fact that in both cases, an upper-level structure reaches the confluent zone. Its interaction with the low-level flow is indicated by the orange contour, the baroclinic conversion term. The fields are 850 hPa relative vorticity (purple contours and shading) and selected isotherms of moist potential temperature (red contours). Adapted from Arbogast, Ph., 2004. Frontal wave development by interaction between a front and a cyclone: application to the FASTEX IOP 17. Quarterly Journal of the Royal Meteorological Society 130, 1675–1696, published by John Wiley & Sons Ltd.

iso- θ'_w) to be intense as well, which accounts for the extremely rapid initial growth of Low M.

This way, the understanding of real cases makes new ground, with the possibility to actually demonstrate growth mechanisms.

Possible Mechanisms for Rapid Growth in Jet Stream Diffuence Zones

The latter subsections have mostly considered mechanisms for initiation. The general idea of baroclinic interaction would suggest that, when it takes place, the larger the baroclinity, the most efficient it will be. But that is not what is observed. What is observed in the initial case of Low M, in the maturation phase of the composite cyclone A or in the ERA40 North Atlantic trajectory set, and from other sources as well is that growth takes place somewhat downstream of the largest baroclinity, furthermore in a large-scale diffuent environment where consequently baroclinity weakens. There is also the fact that part of the lows cross the jet axis during this growth phase in a diffuent zone.

This is the problem of understanding the localization of the baroclinic interaction in the real atmosphere. Some mechanisms have been brought out by revisiting the barotropic and baroclinic energy source terms presented earlier. These are well-known expressions, but they have many sides. The following results from interpreting those terms first as necessarily dominant ones when a balanced perturbation grows in a balanced environment and second, locally, without making any assumption on the representation of the perturbation, whether it is a wave or something else. Starting with the barotropic interaction in a weakly curved flow, the contribution of the environment is shown to depend on a key property called the effective deformation $\bar{\Delta}$. It is defined as:

$$\bar{\Delta} = \bar{D}_f^2 - \bar{\zeta}^2, \quad [11]$$

where $\bar{\zeta}$ is the vorticity of the environment and $\bar{D}_f$ is the magnitude of the deformation field of the environment.

Upper-level anomalies are being tracked along the poleward side of the jet stream, as seen for example in the case study. However, this is an area of large deformation. Applying basic reasoning, this should rapidly stretch any structure in this area to the point it cannot be seen any more. Yet, these also are regions of large vorticity due to the shear. The fact that it is the difference between these two properties that is dynamically relevant, both being large on both sides of the jet, explains why structures can be followed.

As seen above, the other key aspect of barotropic interaction is the horizontal shape of the perturbation, through the E' vector. So this subsection sets on the front scene the deformation as a key property of the environment and the shape of the perturbation interacting with it. The deformation is important in regions of diffuence, confluence, and shear. It plays an important role in the quasi-geostrophic framework in the forcing of vertical velocity. What is meant by shape is the existence of anisotropy or aspect ratio. Both the deformation and the shape can be characterized by directions of dilatation or elongation normal to directions of contraction or reduction: these special directions are the principal axes.

Positive values of $\bar{\Delta}$ correspond to regions where cyclones can be strongly stretched because of the deformation action, and where barotropic processes can be very important.

In regions of negative $\bar{\Delta}$, barotropic processes are quite weak. It is observed that cyclones tend to be trapped in areas of positive values of $\bar{\Delta}$.

The baroclinic interaction, on the other hand, is locally proportional to $\bar{B}F' \cos(\mathbf{F}' \bar{\mathbf{B}})$, where $\bar{B}$ and F' are the magnitudes of $\bar{\mathbf{B}}$ and $\mathbf{F}'$ given by eqns [8] and [7].

The idea is that a situation that leads to the shape of the cyclone perturbation to change or to change the way it is aligned with either the environment effective deformation or the environment baroclinity can more than compensate for a decreasing baroclinity and generate growth. Two mechanisms at least have been proposed along this line. Both ultimately lead to improve the baroclinic interaction. One does this by first allowing for a strong phase of transient barotropic growth that recreates a vertical tilt with height. It nicely explains the main growth phase of the FASTEX case the initiation of which has been explained in Figure 28. The other is summarized schematically in Figure 29. The presence of the diffuence zone reduces the horizontal distance between the upper and lower parts of the structure of the environment baroclinic zone (the slope of the iso- θ and other fields become more vertical). As the cyclone tends to cling to the lower baroclinic area, on the side where effective deformation is positive, it is also brought closer to the jet axis. This improves the alignment of the perturbation with the baroclinity, which explains the baroclinic growth. Such a configuration is called a baroclinic critical region. It seems to apply to the Low M case study.

The crossing of the jet stream by some of the cyclones has furthermore be the focus of recent idealized simulations. The main result is that this is a deeply nonlinear process. Nonlinear interaction terms seem to be more important for the crossing to take place than the presence of diffuence.

Upstream–Downstream Influence of the Flow on Cyclone Development

So far, the quasi-local influence of coherent anomalies in a baroclinic flow has been stressed. However, most of the structures considered are dispersive. This means that the energy converted when a baroclinic interaction takes place may propagate at a group velocity, which is different from the average phase speed of the structures involved. This is called the upstream–downstream influence on cyclone development.

For an idealized situation – a purely zonal flow, for example – consider an amplifying isolated cyclone. Upstream and downstream development takes the form of a train of anticyclones and cyclones that begin to form and develop both downstream and upstream of the original system.

In the real atmosphere, this means that the growth of a cyclone may not only be controlled by its local conditions; the presence of another system may be important as well. The easiest mechanism to diagnose is the downstream influence of a rapidly growing cyclone near the east coast of America (say) on a cyclone close to Europe. Examples of upstream influence are still to be found.

Cyclone Substructures and Air Streams

So far, the presentation focused on the cyclones as a whole and on their links with their larger scale environment. However,

Figure 29 One possible mechanism accounting for the development of an extratropical cyclone in a region of diffluence (or exit) of the environment jet stream, when it is organized as a *baroclinic critical region* (BcCR). The large-scale flow making a BcCR is such that reducing the speed of the jet as one nears the exit implies, in a balanced atmosphere, that the vertical slope of a number of properties such as isentropes or absolute momentum surfaces increases: the low-level jet closes on the location of the upper-level one. A cyclone moves through it, shown by the four-step sequence of heavy solid contours of vorticity or geopotential. This implies that, as the system nears the exit area, its low-level component tends to close on the upper-level one and to align with it in the direction of the large-scale baroclinicity (step 2 and step 3). At step 3, provided the upper-level component remains upstream, the vertical structure is in line with BcCR so that it is optimal at least for that component of the baroclinic source term, and growth is increased, possibly significantly, depending on the other aspects. Adapted from Rivière, G., Joly, A., 2006. Role of the low-frequency deformation field on the explosive growth of extratropical cyclones at the jet exit. Part II: Barotropic critical region. *Journal of Atmospheric Sciences* 63, 1982–1995.

cyclones, especially mature ones, are in themselves a world inhabited by different kinds of smaller scale organizations of the atmospheric flow. A presentation of extratropical cyclones would not be complete without mentioning some of these substructures.

Fronts

One kind of such airflow organization that is intimately linked to extratropical cyclones is atmospheric front. The name means that, when one is overpassed by an atmospheric front, one observes very rapid changes of the atmospheric conditions. In the case of a cold front, for example, the temperature drops, the pressure rises, the sky changes from overcast and low to quite clear, and the wind turns and its speed either rises or falls. All these events happen suddenly, quasi simultaneously.

The concept of front replaces with one word and one picture this list of closely related evolutions of many individual fields. It is this concentration of rapid changes or large gradients that really is the hallmark of a front. It is a well-observed feature. Returning to Low M in the Pacific Ocean provides some examples of fronts. **Figure 30** pictures several aspects of the low-level structure of that cyclone at the time its core vorticity is largest. Except in the cores of Low M and the remnant of Low P, vorticity is organized in narrow bands (less than 200 km) reaching values of $2f$ and more. Having in mind that the fields are truncated, this is an underestimate. The moist potential temperature gradients, averaged over the whole period of the case study reach a value of $6 \text{ K}/500 \text{ km}$ below the mean jet-stream core ($1.1 \times 10^{-5} \text{ K m}^{-1}$). In two places of Low M

at that time, these same gradients reach $10 \text{ K}/150 \text{ km}$ ($6.5 \times 10^{-5} \text{ K m}^{-1}$). Notice also that these areas of very large gradients and of vorticity are superimposed, they also coincide with very neat boundaries of saturated air. The wind is also shown. Where the θ'_w horizontal gradient is strongest, it reaches 55 kt (28 m s^{-1}) in a narrow southwestern extension close to the vorticity band. Closer to the core, a kind of low-level jet is present with southwesterly wind reaching 75 kt (39 m s^{-1}). These confined areas are also places of strong turbulence. All these aspects are graphically translated by frontal and other symbols, a way to compact quite a lot of information.

However, it is also important to note that these fronts are quite limited both in space and in time. They really are embedded in the cyclone and are present only in portions of it. Their presence is also temporary, as can be seen, for example, in **Figure 7**. It shows that the cold front is still strong and has gained extension on 01/04 at 06UTC but then weakens significantly during the following 24 h. It is important to point this out because during most of the twentieth century, fronts have been depicted as planetary scale semipermanent organizations, indeed the large-scale environment from which extratropical cyclones emanated. To some extent, there is a planetary scale but quite weak front, the low-level signature of the jet-stream flow on the meridional temperature gradient. But it is better to draw a line between this view and the current one for the following reasons. First, the locally well-observed rapid changes that mark a front are definitely not observed on the planetary scale: using the same word for very active and quite peaceful environments simply weakens the concept to the point of making it useless. Second, the growth mechanism that could sustain cyclones

Figure 30 Details of the low-level organization of Low M at the time it reaches its maximum development, showing the presence and the structure of atmospheric fronts. Top panel: 850 hPa relative vorticity (purple contours and yellow to red shading, as in [Figure 6](#)), mean sea-level pressure (black contours as in [Figure 1](#)), 850 hPa moist potential temperature (dark red contours, interval 2 K), and wind at the same level (light blue barbs and shading with scale in the panel). Middle panel: pressure, 850 hPa moist potential temperature and wind superimposed on relative humidity at 700 hPa (green shading, scale in the panel). Bottom panel: the characteristic features that can be seen in these fields are graphically translated in this last map. The most important ones are the fronts, most intense when combining large temperature gradients, vorticity, and strong winds. The large arrows indicate low-level jets. The double blue line stands for the upper-level jet, with indication of a diffluent zone. The graphical code is from Santurette, P., Joly, A., 2002. ANASYG/PRESYG, Météo-France's new graphical summary of the synoptic situation. *Journal of Applied Meteorology* 9, 129–154.

growing from a large-scale front is primarily barotropic, and this, among other many things, cannot lead to large pressure deepening. Only baroclinic conversion taking place over the depth of the troposphere can allow for this.

So atmospheric fronts are transient features that result from the development of extratropical cyclones. The mechanism that leads to this is now well understood. It is an inherently nonlinear process that is to a large extent explained by an elegant extension of the quasi-geostrophic framework, the semi-geostrophic theory. The main aspect that needs to be added to this theory in its simplest form in order to obtain idealized fronts quite close to observed ones is latent heat in the ascents.

Fronts result from a positive feedback between the geostrophic forcing of the ageostrophic circulation and that circulation in the presence of a boundary. Recall that the ageostrophic circulation sets up in the sense of limiting the geostrophic flow tendency to weaken thermal wind balance: an ascent (say) reduces the geostrophic warming resulting from a poleward flow in the presence of a meridional temperature gradient. However, close to a boundary such as the surface, vertical motion is geometrically limited, so the countering action is not efficient. At the same location, however, a growing horizontal ageostrophic convergent flow is required to provide air to the ascent base as requested by mass conservation. The action of the deformation is poorly controlled, so its effect increases, so the response in vertical motion also increases. This implies that the horizontal convergence also grows, and reaches amplitudes such that its own advective effect on the thermal field cannot be ignored any more, as it is in quasi-geostrophic balance. It brings the extra contribution to

increasing the gradients that lead, in an idealized flow, to infinite gradients in a finite time. This theory indicates that fronts initially form near boundaries such as the surface or the tropopause, and possibly extend into the troposphere.

System-Relative Air Streams

So far, the description of extratropical cyclones and of their growth mechanism has been given in terms of coherent flow organizations such as vorticity extrema, wind field, and the likes. These structures can be represented mathematically by waves or, rather, by wave packets. They can be tracked and their interactions can be evaluated. This is a useful framework for understanding the basic adiabatic dynamics operating in cyclones.

However, some aspects of the description of the associated weather, namely the cloud and precipitation patterns, the origin of the air involved in a cyclone circulation does not fit well into this framework. They seem to come last in a long chain of dynamical causes and effects, while these properties come first in terms of noticing the weather.

In other words, most of this article describes cyclones in terms of Eulerian-based fields. However, the associated motion displaces air parcels that carry with them a number of properties such as their water content, initial temperature, and location. The fact is the motion of the Eulerian coherent structures in fields, that can be described by dispersion equations, has little or nothing to do with the actual motion of air parcels relative to the system. Yet, this is of interest to complete the picture.

Figure 31 Overview of the main air streams that can be observed within a baroclinic wave, relative to the system (large arrows). The sloping surface that supports them is a surface of constant potential temperature θ , or rather, of constant moist potential temperature θ'_w . From Thorncroft, C.D., Hoskins, B.J., McIntyre, M.E., 1993. Two paradigms of baroclinic-wave life-cycle behaviour. *Quarterly Journal of the Royal Meteorological Society* 119, 17–55, published by John Wiley & Sons Ltd.

Taking the large-scale view, it has been thought that a cyclone involved two basic air streams relative to its overall structure (Figure 31). One involves the warm air, which comes from low latitudes and low levels, ascends while going through the cyclone core and escapes the cyclone either westward (moving more slowly than the cyclone) or eastward (when moving more rapidly than the cyclone) in an outflow jet. The other air stream has a poleward, stratospheric origin and descends toward the westward side of the cyclone where it splits into two branches, one reaching for low latitudes and low levels, the other moving toward the cyclone core, possibly reascending. Because of its origin, this air is very dry. The splitting pattern can be seen on satellite images in the form of a dry hammer-shaped feature. The scale of these streams is of the order of L_R .

A more general approach has been developed in order to explore the existence of actual coherent air streams relative to real cyclones. A series of Eulerian analyses are used to compute

a large number of air parcel trajectories, emanating from almost everywhere, over the lifetime of a given cyclone of interest. A number of properties are then interpolated to these individual trajectories: their location in 4D space, of course, but also their potential temperature, water vapor content, potential vorticity, etc. Then, a given objective criterion is selected, such as 'trajectories that ascended the most' during the selected period, or 'trajectories with parcels that lost the most water vapor' or those that 'underwent the largest descent.'

The extraordinary thing is that, when trajectories are selected in this way, they appear not to be randomly distributed but to be concentrated into coherent ensembles of trajectories for a lapse of time of the same order as the time of a cyclone development. This strongly supports the idea of the existence of coherent air streams relative to cyclones. Some actual examples are shown in Figure 32.

Consider the warm air stream of the broad view. The 'coherent ensemble of trajectory' view reveals a very large relative change of location between the stream and the developing cyclone. The warm air stream that reaches the core of the cyclone at the mature stage is made of air that comes from low latitudes and low levels far away to the east of the incipient cyclone when it starts to form.

The broad picture, however, is confirmed. The main idea to keep is that, while the shape of a cyclone is made up from coherent structures of the flow that propagate in a roughly zonal direction, the air that is mixed within its core is brought by parcels that move mostly meridionally, which is not completely intuitive. The stronger the cyclone, the more directly meridional air parcels converge toward its core at the mature stage.

Example of Recent Concept: The Sting Jet

The detailed study of high-resolution satellite image of cyclones or of radar measurements reveals a wealth of meso- and small-scale features within these air streams. Some of these can

Figure 32 Objectively computed coherent ensembles of trajectories between 22 November 00UTC and 24 November 1992 00UTC. At the final time, there is a cyclone south of Iceland; the trajectory of the minimum pressure during the same 48 h is shown by the linked circles. The air trajectories are absolute, not relative to the system, they are derived from a series of three-dimensional analyzed fields. Left: trajectories undergoing an ascent larger than 620 hPa. Right: trajectories descending more than 380 hPa (southernmost ones in brown) and descending more than 350 hPa with initial potential vorticity larger than 2 pvu together with a third ensemble of descending trajectories keeping a large potential vorticity (northern ensembles in orange). Adapted from Wernli, H., 1997. A Lagrangian-based analysis of extratropical cyclones. II: A detailed case-study. *Quarterly Journal of the Royal Meteorological Society* 123, 1677–1706, published by John Wiley & Sons Ltd.

be seen in the MODIS image of Low M (Figure 2). Precipitations, for example, captured by the radars look like bands, continuous or dashed, much more narrow than the clouds within which they are. It is not possible to detail here the numerous ideas that have been proposed to account for these facts.

Rather, it is interesting to focus on a small-scale aspect of extratropical cyclones that has received attention in recent years. This is because this aspect is significant from the point of view of the destructions caused by stormy cyclones. Indeed, it has been noted that the most destructive part of an extratropical cyclone is not related to the low-level jets associated to its cold or warm front. It happens in the clearer, colder air at the rear of a passing cyclone. Seeing atmospheric conditions improving, one would think that the event is closing to an end (locally speaking), yet the wind brutally increases to gale force, with intense gusts. It results in many damages, more important ones than those caused by other parts of such storms, that form a finite track of wrecks along the path of the cyclone.

The largest scale signature of such a feature is a local extra increase of the pressure gradient to the west or southwest of the minimum pressure of a cyclone moving east. Because it hits so to speak from the rear, it is called a sting jet like 'the sting at the end of the tail.'

Figure 33 is a schematic showing how this feature is currently understood. The extra intensity of the wind would result from rapidly descending air hitting the surface, as if falling and then splashing on the ground. The reason why the subsidence would have been turned into rapid descent is that this air would have moved below the hooking end of the ascending core, which in that area is well away from the ground. This

Figure 33 Schematic showing how the small-scale organization of precipitations within an extratropical cyclone may lead to an area of very strong surface wind at the rear of the system that can be destructive, termed *sting jet*. The large green arrows represent moist ascending air, the ascent zone being subdivided into narrower bands. Interspaced with those are streams of descending air that can be cooled by evaporating rain or snow falling from the moist bands (large orange arrows): this can strongly accelerate the descending motion and, when reaching the ground, suddenly reinforces the surface wind as this very cold air spills on the ground (blue strong wind arrow symbols). Also shown are two vertical cross sections in the system. Adapted from Browning, K.A., 2004. The sting at the end of the tail: damaging winds associated with extratropical cyclones. *Quarterly Journal of the Royal Meteorological Society* 130, 375–399, published by John Wiley & Sons Ltd.

ascending air is precipitating, and it is the evaporation of those precipitations in the dry descending air that would cool it, create negative buoyancy and push it downward.

Extratropical Cyclones and the General Circulation

This final section addresses questions such as why the weather takes the form of cyclones at middle and high latitudes. It is then useful to attempt to understand the evolution of weather on the slightly longer timescale of the order of the week to the month.

Why Extratropical Cyclones?

Atmospheric motions result from and redistribute the inhomogeneous input of energy from the sun, which is in excess at low latitudes and in deficit at high ones. A planetary scale, purely meridional overturning of air, with ascent about the Equator and descent near both poles could both perform the desired redistribution and be energetically self-consistent. However, the spinning of the Earth precludes such a simple meteorology and introduces strong mechanical constraints. These can be understood in terms of angular momentum of air parcels about the axis of rotation of the Earth. To first order, neglecting friction, the only source of absolute motion is the pressure difference between two regions. In the simple overturning model assuming zonal homogeneity, the pressure force is directed toward or away from the axis of rotation; its moment is zero and therefore air parcels moving toward or from the axis conserve their angular momentum. The angular momentum has two components: one relates to the local value of the planetary rotation and the other to the angular momentum of the motion of the parcel relative to the planet normal to the axis (zonal, that is). Thus, the conservation of angular momentum implies a characteristic zonal wind distribution: it turns out to be completely unrealistic with unobserved values at latitudes higher than about 25°. In other words, angular momentum cannot be conserved and atmospheric motions redistribute both energy and angular momentum.

Angular momentum exchanges between air parcels moving away from and toward the axis of rotation require a component of a body force, the pressure force, that is not directed toward the axis – in other words, that has a zonal component. The pressure and other related fields must have zonal variations. Together with the meridional distribution, this leads to alternate cells of high and low pressure at midlatitudes and high latitudes. Hence the vortex-like overall shape of the structures where these exchanges of heat and angular momentum take place.

As has been discussed above, the scale of extratropical cyclones and anticyclones implies that they evolve close to some balanced state of the atmosphere. Among other consequences, low-pressure zones turn out to be rather associated with ascending motion, and therefore clouds and rain. This makes them more 'weatherly' than anticyclones.

Feedback of Cyclones on the Large-Scale Flow

Extratropical cyclones can be seen as synoptic and subsynoptic scale perturbations of the large-scale flow. A short summary

of the main exchange terms has been provided above, in eqns [7]–[10]. Those same terms appear on the large-scale evolution side, except the perturbation components, the fluxes, is averaged and the signs are reversed. The fact that cyclones transport heat upward and poleward at mid and higher latitudes can be quantitatively verified by computing such fluxes. While this is quite frequent and generally easy, in idealized studies, finding characteristic results in case studies is less easy. Figure 34 is such an example. The case, or the period rather, illustrated by this figure pertains to the Southern Hemisphere as its circulation seems closer to a simple flow over a mountainless planet: comparison with idealized studies may be easier. The expected poleward heat flux is indeed present when the main system develops. There is also a large poleward flux of zonal momentum, a component that may modify the jet flow within which the cyclone evolves. This is the main aspect addressed in this section.

The emergence of long homogeneous reanalyses has enabled, on this topic as well, to provide a much-improved view of the behavior of real cyclones. The question has been originally considered in the first consistent framework for understanding cyclones mentioned in an earlier section above: how cyclones may influence the zonal flow within the quasi-geostrophic approximation. In this case, the averaging operator is essentially a zonal mean. The zonal (large scale) wind and temperature distributions can be influenced by

cyclones through spatial operators acting on the Eliassen–Palm flux $\mathcal{F}_{EP}$:

$$\mathcal{F}_{EP} = \left(-[u'v'], \frac{g}{\theta_0 N^2} [v'\theta'] \right), \quad [12]$$

where the operator $[\cdot]$ is a zonal mean. The two ‘components’ of this pseudovector are defined in a meridional vertical cross-section oriented northward and upward. The relationship between the divergence (in the meridional plane) of that vector and the evolution of the zonal large-scale flow is in fact nontrivial at all. This is further complicated by the existence of imposed cancellations between perturbation contributions through fluxes and large-scale flow only processes.

The focus now is less on the zonal flow than on critical zonal inhomogeneities of the jet flow, as discussed previously. In order to study 3D or 4D large-scale flows, the relevant averaging operator locally selects chosen time and/or spatial scales. A popular way to separate the flow into a large-scale environment and perturbations using time series of gridded fields such as reanalyses is by using time filters on each grid point time series. This kind of separation enabled to unveil characteristic patterns of the large-scale flow. The question of the feedback of the cyclones becomes that of understanding whether cyclones are contributing to the maintenance of these large-scale patterns or whether they can explain their changes. This turns out to be a very complex question that remains open in several aspects.

The large-scale flow patterns have been extracted in various ways. One statistical approach is to perform a classification or clustering of the day-to-day low-pass time-filtered maps of the large-scale flow. Some of these organizations can be given some dynamical meaning either a posteriori by applying a proper forcing to simplified atmospheric models and studying the response. Alternatively, characteristic large-scale patterns have also been obtained directly from dynamical constraints, such as finding structures that are quasi stationary by minimizing their time-evolution tendency. It is convenient here to distinguish between very large-scale patterns, the dominant shape of which will characterize the large-scale flow of, say, a season and other such patterns that are reasonably steady or propagate slowly with a time constant between a week and 10 days. The former have received names such as the North Atlantic oscillation or the Pacific North American oscillation. The latter are sometimes called weather regimes. As their name suggest, large-scale oscillations correspond to large-scale anomalies with similar shapes but opposite signs, a kind of two-state oscillation. Weather regimes have richer structures. For example, many different techniques, statistical, dynamical, or mixed yield from different data sources four quite robust structures preferred by the large-scale flow over the North Atlantic basin. The large-scale flow in that area can be seen as periods dominated by one of these four flows or regimes that seems steady for several consecutive days, sometimes weeks followed by relatively rapid transitions from one regime to another. Here, ‘rapid’ means that the change occurs in a matter of 2 or 3 days. The large size of the North Pacific basin requires extended techniques for regimes to be found: while regimes are indeed stationary in the North Atlantic, they propagate as large-scale Rossby waves in the North Pacific. The separation between oscillations and

Figure 34 Latitude-time sections of the zonally averaged northward heat flux at 700 hPa in K m s^{-1} (top panel) and northward momentum flux at 300 hPa in $\text{m}^2 \text{s}^{-2}$ (bottom panel) for zonal wavenumbers 5–7. Negative fluxes are directed poleward, as indicated by the large arrow, since this is a Southern Hemisphere case study. The day of maximum activity, day 9 on the panels, is 13 December 1979. Adapted from Randel, W.J., Stanford, J.L., 1985. The observed life cycle of a baroclinic instability. *Journal of Atmospheric Sciences* 42, 1364–1373.

regimes is not as clearcut as presented here for simplicity: some authors choose to ignore the distinction and characterize all large-scale variability with the oscillations patterns.

These large-scale patterns determine the overall configuration of the jet stream over a given stormtrack area: location of main jet entrance and exit zones, therefore extent as well as orientation and curvature of the jet. This will considerably influence the trajectories and main phases of the synoptic scale cyclones, following the mechanisms outlined in previous sections.

The adiabatic part of the feedback of the cyclones on these 3D patterns, on the other hand, depends on the pseudovector $\mathbf{E}$:

$$\mathbf{E} = \left(\mathbf{E}', \frac{g}{\theta_0 N^2} \overline{v'\theta'} \right),$$

where $\mathbf{E}'$ is the horizontal vector defined by eqn [9]. Here, the $\overline{}$ operator is a time average or a scale average that keeps some of the zonal variability. To be more precise, the meridional component of the gradient of the divergence of $\mathbf{E}$ is one of the two major terms forcing the evolution of the large-scale potential vorticity field. It is indeed the major contribution to the divergence of the meridional flux of the perturbation potential vorticity. These results approximately hold at the level of the quasi-geostrophic approximation. At a similar level of approximation, the $\mathbf{E}$ pseudovector has a number of interesting heuristic properties that have been hinted previously. In a balanced flow, $\mathbf{E}$ depends on the horizontal and vertical tilts of the perturbations. When the $\mathbf{E}$ vector is oriented westward (or in the direction of the large-scale flow), the associated perturbations tend to be stretched in directions normal to $\mathbf{E}$. Namely, they are elongated meridionally. The trough associated to the perturbation tilts horizontally normal to a westward $\mathbf{E}$. The group velocity vector of the perturbations, in the same context, is close to $\mathbf{E}$, given a known acute angle. Recall also that the 'vertical' component of $\mathbf{E}$, the meridional heat flux, is related to the vertical tilt of the perturbations.

Figure 35 shows the distributions of momentum fluxes and of $\mathbf{E}$ pseudovectors at the eastern end of the Pacific stormtrack

and over the North Atlantic stormtrack. The perturbations highlighted by this figure have characteristic timescales between 2 and 5 days. At these scales, the momentum fluxes are strongly poleward at the southeastward end of the stormtracks, but equatorward fluxes in the northwestern and central part of the stormtrack. The $\mathbf{E}$ vectors are clearly pointing eastward, northeastward in the northern part of the stormtrack, southeastward in the southern end. This corresponds to perturbations generally taking a meridional extension. This configuration is in the sense of increasing the vertically averaged zonal flow at the entrance and heart of the North Atlantic stormtrack.

There are, however, limitations to these approaches that can be perceived even at the level of this very short account. Just as with the Eliassen–Palm flux and the zonal mean circulation, it is not obvious to go from the distribution of $\mathbf{E}$ to the change in the jet flow. Indeed, the large-scale kinetic energy evolves depending on the correlation between the large-scale zonal flow $\bar{u}$ and $\nabla \cdot \mathbf{E}$, so that a given distribution of $\mathbf{E}$ does not have the same effect on its environment if the latter is different. Furthermore, $\mathbf{E}$ vectors can be constructed for different scales, depending on the averaging operator chosen. These lead to another limitation: it happens that varying the scales of perturbations analyzed in this way yields quite different distributions of $\mathbf{E}$. The difficulty comes from the fact that the scale of cyclone perturbations changes significantly: as it moves through the stormtrack and grows, it tends to gain a larger scale.

These are some of the reasons why, recently, a heuristic understanding of the feedback of cyclones on the jet flow has favored a complementary approach allowing this feedback to be more easily anticipated at case study level. The idea is that cyclones near the end of the stormtrack reach their maximum amplitude and interact in a nonlinear way with their environment. They also tend to lose their baroclinic tilt and behave in a more barotropic way on the vertical, with maximum amplitudes in the upper troposphere. Looking at their evolution on a semihorizontal surface, such as a constant potential vorticity surface or the poleward part of a surface of constant potential

Figure 35 Properties of perturbations resulting from selecting the 2–5-day period when time-filtering the NCEP–NCAR 1950–99 reanalysis fields at 00UTC and 12UTC, December–February. Characteristics of the Atlantic storm-track eddy activity and its relation with the North Atlantic oscillation. *Journal of Atmospheric Sciences* 64, 241–266.

temperature, this late part of their evolution looks like they are breaking waves.

It turns out that there are essentially two ways for mature cyclones to break as waves and strongly interact with the jet flow. This has been initially uncovered in an idealized study of cyclone life cycle, but it appears to be representative of observed behaviors.

Figure 36 summarizes with a single contour these two kinds of behavior and their main effect on the jet flow. One was originally called life cycle 1 (LC1) and it evolves into an anticyclonic wave breaking. It is characterized by the development of an upper-air trough that is significantly stretched with a northeast–southwest orientation. The sketch in the figure is based on a single contour of a quasi-conservative parameter (such as potential vorticity or absolute vorticity) on a quasi-conservative surface that summarizes the overall shape of the total flow locally dominated by the cyclone perturbation. Superimposed is the corresponding cyclonic upper-tropospheric vorticity anomaly, which is also stretched. From this, assuming that these perturbations are essentially nondivergent (consistent with quasi-geostrophic ideas), it is easy to recover the associated momentum flux that appears to be consistent with the jet displacement relative to the system. An anticyclonic wave breaking is associated with momentum fluxes converging on the poleward side of the jet (and diverging on the equatorward side). This results in shifting the jet poleward. In this situation, the amplitude of the surface cyclone tends to decrease rapidly as the upper-air part cuts off from the main flow, prior to being stretched out.

The other life cycle, called life cycle 2 (LC2), leads to cyclonic wave breaking. In the upper troposphere, the cyclonic perturbation remains tilted northwest–southeast while expanding in scale. In this case, momentum fluxes diverge on the poleward side, converge on the equatorward side: the jet is shifted equatorward. During this kind of breaking, the cyclone kinetic energy peaks at larger values than those reached by anticyclonic wave breaking. The resulting large-scale cyclonic trough also tends to persist, while moving poleward.

As the schematic shows, to some extent, the views provided by E vectors and contour dynamics are complementing each other. However, because the latter directly shows such things as a local change of sign of the gradient of a conservative variable such as potential vorticity, it directly implies a change in the background flow, effortlessly selecting only the events the amplitude and scale of which do lead to serious feedback.

Recently, automatic detection of wave breaking using contour tracking in reanalyses has enabled to build composites of such situations. In the North Atlantic basin, consistently with **Figure 35** above, cyclonic wave breaking is favored in the northwestern part of the winter stormtrack, while anticyclonic wave breaking is frequent in the southeastern part, close to or aloft southwestern Europe and the western Mediterranean. On average, anticyclonic wave breaking is the preferred evolution, implying a poleward shift of the jet at the end of stormtracks that is indeed noted. Indeed, returning again to the example of Low M in the northern Pacific, **Figure 37** shows it as a realization of an anticyclonic wave-breaking event.

There are many aspects of the dynamics that influence the type of wave breaking. It must be noted, for example, that from

Figure 36 Time sequences summarizing with a single contour representative of the upper-tropospheric flow configuration two paradigms of the nonlinear phase of extratropical cyclones. that perspective, the quasi-geostrophic approximation has clear shortcomings with respect to the more precise primitive equation dynamics (with hydrostatic balance as the only scale assumption). The latter introduces an initial bias of the incipient cyclones toward a cyclonic horizontal tilt that the former is not able to provide. Sphericity and latitude also may influence the type of wave breaking through, for example, the so-called stretching term in the evolution of perturbation vorticity.

Initially, however, the key parameter appeared to be the presence of a barotropic horizontal shear component in the jet flow. That is what led idealized simulations to yield either an LC1 or an LC2. The favored breaking is determined by the sign of the shear: cyclonic shear leads to cyclonic wave breaking. However, the amplitude required is not symmetric at all. A small anticyclonic shear is sufficient to lead to anticyclonic breaking, while a large cyclonic shear is needed to reverse that preferred behavior. However, the latitude of the jet, its intensity, its width are also critical. For example, a more poleward jet further favors anticyclonic wave breaking.

These ideas are useful to understand some aspects of the changes of the climate in relation to stormtracks. Using the conceptual tools summarized in this section, it has been shown in both idealized and observation-based studies that small and moderate amplitude cyclones forming within a given large-scale pattern such as a weather regime are shaped in such a way that they have a positive feedback on the maintenance of that regime. In other words, the average cyclone contributes through its heat and momentum fluxes to the persistence of the regime. Whether large amplitude systems behave similarly or conversely trigger regime transitions remains an open question, in spite of a number of single-case based reports.

Fronts

Synopsis

Traditionally, fronts have been defined as boundaries between air masses. Because this definition can be problematic in a modern context, a new definition is proposed. A front is a region characterized by frontogenesis containing both a horizontal potential temperature gradient and vorticity maximum. Fronts are classified as surface based or upper level. Surface-based fronts are further classified as those associated with synoptic-scale phenomena (cold, warm, stationary, or occluded) or those associated with mesoscale phenomena (sea breeze, gust, or drainage). Front-like features such as drylines also exist.

Introduction

The traditional definition of a front is the boundary between two different air masses, which are large bodies of near-surface air extending for hundreds or thousands of kilometers with nearly uniform temperature, moisture content, and static stability. Air masses are classified by where they originate from and the surface underlying their origin (i.e., polar vs tropical, continental vs maritime). Being the boundary between two different air masses means that fronts are often regions where changes in temperature, pressure, moisture content, and wind occur over small distances. Fronts can also be associated with precipitation. Thus, for these reasons, identification and tracking of fronts are crucial for weather forecasting.

This traditional definition of fronts was developed by Norwegian meteorologists in the 1910s and 1920s studying the structure and evolution of extratropical cyclones (Bjerknes, 1919; Bjerknes and Solberg, 1922). Using the terminology of the recent First World War, fronts were lines on a map drawn where the clash of cold and warm air masses occurred. Although abrupt changes in wind and temperature had been previously recognized before the Norwegians (e.g., historical reviews by Bergeron, 1959; Kutzbach, 1979, Section 6.7; Davies, 1997; Newton and Rodebush Newton, 1999; Volkert, 1999), the Norwegians were the first to embed fronts as the unifying concept within the three-dimensional structure and evolution of extratropical cyclones.

Toward a New Definition

In a modern scientific context, however, this traditional definition can be problematic. First, fronts do not always form along the edge of air masses, but may form within air masses. Because the air near the surface may not be easily classified into large regions of nearly homogenous properties, even within well-defined air masses, gradients of temperature and wind may be present and could be considered to be fronts. Thus, we seek a definition of a front that could allow for the existence of fronts within an air mass.

Second, although boundaries between air masses may be clear in some cases, what constitutes an air mass or its boundary may not be clear in all cases. As an attempt to address this weakness, some investigators have defined a front only if the horizontal temperature gradient or other higher derivatives of the temperature gradient exceeds strict thresholds (e.g., Hewson, 1998; Sanders, 1999; Sanders and Hoffman, 2002). Although such approaches automate the analysis and detection of fronts, they do not help better understand the processes affecting fronts and their intensity or why fronts form where they do.

Third, the large horizontal scale of air masses implies that fronts – as the boundaries of these air masses – must possess the same characteristic scale: large mesoscale or synoptic scale in the along-front direction (200–2000 km) and small mesoscale in the across-front direction (20–200 km; Keyser, 1986). Not all fronts, however, may be this large; some fronts may be small mesoscale in the along-front direction and microscale (2–20 km) in the across-front direction. Thus, the traditional definition may exclude smaller scale features that share the same physical processes and deserve to be considered fronts, as well.

Finally, and perhaps most significantly, the traditional definition of a front as the boundary between air masses forced meteorologists into an unproductive game of arguing over where to draw the line on the map representing the front, rather than focusing on the relevant physical processes creating and maintaining the front and associated sensible weather (e.g., wind shifts, temperature changes, precipitation). Part of the dilemma with frontal analysis is that the characteristics of fronts used for analysis are not clearly defined, allowing any number of plausible analyses (e.g., Uccellini et al., 1992; Sanders and Doswell, 1995; Lackmann, 2011, Section 6.1). Some have raised issues with synoptic analysis (e.g., Mass, 1991; Sanders and Doswell, 1995; Sanders, 2005), and others have proposed alternative analysis schemes, particularly to deal with fronts associated with mesoscale phenomena (e.g., Colby and Seitter, 1987; Young and Fritsch, 1989). Manual analysis of weather maps is a crucial step to producing a weather forecast, but it is ultimately subjective and its overemphasis has probably inhibited a more modern approach to frontal analysis (e.g., Sutcliffe, 1952; Mass, 1991; Schultz, 2008).

[†] Deceased.

An alternative approach is a mathematical one. Petterssen (1936) defined frontogenesis as the Lagrangian rate of change of the magnitude of the horizontal potential temperature (θ) gradient due to the horizontal wind ($\mathbf{V}_2 = u\mathbf{i} + v\mathbf{j}$):

$$F = \frac{d}{dt} |\nabla_2 \theta|, \quad [1]$$

where

$$\frac{d}{dt} = \frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y},$$

$$\nabla_2 = \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y}.$$

This mathematical definition of a front emphasizes that both the temperature field and the wind field are responsible for producing frontogenesis.

For these reasons and to update the traditional definition, a modern definition of a front is proposed that combines the physical and mathematical approaches (e.g., Keyser, 1986; Sanders, 1999; Lackmann, 2011). A front is a region characterized by frontogenesis containing both a horizontal potential temperature gradient and vorticity maximum. Sometimes, the vorticity is not coincident with the temperature gradient, but often is. The benefit of using frontogenesis in the definition is that it treats fronts as processes, not rigid objects being advected around by the flow, which is an unfortunate result of treating fronts as the boundaries between air masses. If a region contains no temperature gradient or vorticity, then it cannot be a front (Sanders, 1999). If the gradient did not arise through or possess frontogenesis, then it is not a front. This definition also allows for the possibility of fronts forming within air masses and is independent of scale. Finally, this definition alleviates the problem of where to draw the line on the map as regions of frontogenesis are calculated explicitly.

Fronts Associated with Synoptic-Scale Phenomena

The intensity of a front, measured by changes in the temperature and wind fields that occur across the frontal transition zone, is most pronounced at or near the Earth's surface and the tropopause. These fronts occur on the synoptic scale and may retain their individual identities for many hours or even days. The physical processes that give rise to fronts are controlled by four principal forces: the buoyancy force, the pressure gradient force, the Coriolis force, and the friction force, whose influence is primarily restricted to the lowest 1–1.5 km of the atmosphere, the planetary boundary layer. The buoyancy force results from a small imbalance between gravity, which acts downward toward the Earth's surface, and an upward vertical pressure gradient force. When the two are equal in magnitude, hydrostatic balance occurs. The direction of the buoyancy force controls the direction of vertical motions associated with fronts. The horizontal component of the pressure gradient force, which is directed toward low pressure, is largely opposed by the Coriolis force. The Coriolis force is directly proportional to the Earth's rotation rate and to the magnitude of the horizontal wind vector, directed to the right of the horizontal wind in the Northern Hemisphere. These forces tend to be in

approximate geostrophic balance above the planetary boundary layer, providing a counterclockwise circulation around a low-pressure center. The friction force reduces the wind speed within the planetary boundary layer, and lessens the magnitude of the Coriolis force, which leads to cross-isobaric flow toward low pressure.

The language and notation for synoptic-scale surface fronts were created by the Norwegian meteorologists (e.g., Jewell, 1981; Friedman, 1989). The strength of the Norwegian cyclone model was that it created a holistic conceptual model that related the structure and evolution of an extratropical cyclone (low-pressure system) and anticyclone (high-pressure system) with their attendant fronts and sensible weather. In the Norwegian cyclone model, an initial cyclone initiated on a broad temperature gradient (Figure 1). As the cyclone deepens, the circulation around the cyclone increases, bringing cold air equatorward to form the cold front and bringing warm air poleward to form the warm front.

Cold Fronts

The passage of a cold front typically is indicated by a drop in temperature as the advancing cold air replaces warm air (e.g., Sanders 1955; Schultz 2008; Schultz and Roebber 2008). The leading edge of the cold front is delineated by the triangles that point in the direction of movement of the cold air (Figure 1). Conceptual models typically depict traditional cold frontal passages, not only with a temperature decrease, but also with a cyclonic wind change, pressure minimum, and decrease in dew point temperature, all coincident with a line of deep,

Figure 1 Conceptual model of a Norwegian cyclone showing (top) lower-tropospheric (e.g., 850 mb) geopotential height and fronts, and (bottom) lower-tropospheric potential temperature. The stages in the respective cyclone evolutions are separated by approximately 6–24 h and the frontal symbols are conventional. The characteristic scale of the cyclones based on the distance from the geopotential height minimum, denoted by I, to the outermost geopotential height contour in stage IV is 1000 km.
